Intra- vs Intermolecular Photoinduced Electron Transfer Reactions of a Macrocyclic Donor-Acceptor Dyad

MOORE, Evan G., et al.

Abstract

The synthesis, structural characterization, and photophysical behavior of a 14-membered tetraazamacrocycle with pendant 4-dimethylaminobenzyl (DMAB) and 9-anthracenylmethyl groups is reported (L3, 6-((9-anthracenylmethyl)amino)-trans-6,13-dimethyl-13-((4-dimethylaminobenzyl)amino)-1,4,8,11-tetraazacyclotetradecane). In its free base form, this compound displays rapid intramolecular photoinduced electron transfer (PET) quenching of the anthracene emission, with both the secondary amines and the DMAB group capable of acting as electron donors. When complexed with Zn(II), the characteristic fluorescence of the anthracene chromophore is restored as the former of these pathways is deactivated by coordination. Importantly, it is shown that the DMAB group, which remains uncoordinated and PET active, acts only very weakly to quench emission, by comparison to the behavior of a model Zn complex lacking the pendant DMAB group, [ZnL2]2+ (Chart 1). By contrast, Stern–Volmer analysis of intermolecular quenching of [ZnL2]2+ by N,N-dimethylaniline (DMA) has shown that this reaction is diffusion limited. Hence, the pivotal role of the [...]

The synthesis, structural characterization, and photophysical behavior of a 14-membered tetraazamacrocycle with pendant 4-dimethylaminobenzyl (DMAB) and 9-anthracenylmethyl groups is reported (L3, 6-((9-anthracenylmethyl)amino)-trans-6,13-dimethyl-13-((4-dimethylaminobenzyl)amino)-1,4,8,11-tetraazacycletetrade cane). In its free base form, this compound displays rapid intramolecular photoinduced electron transfer (PET) quenching of the anthracene emission, with both the secondary amines and the DMAB group capable of acting as electron donors. When complexed with Zn(II), the characteristic fluorescence of the anthracene chromophore is restored as the former of these pathways is deactivated by coordination. Importantly, it is shown that the DMAB group, which remains uncoordinated and PET active, acts only very weakly to quench emission, by comparison to the behavior of a model Zn complex lacking the pendant DMAB group, [ZnL2]2+ (Chart 1). By contrast, Stern–Volmer analysis of intermolecular quenching of [ZnL2]2+ by N,N-dimethylaniline (DMA) has shown that this reaction is diffusion limited. Hence, the pivotal role of the bridge in influencing intramolecular PET is highlighted.

Introduction

Photoinduced Electron Transfer (PET) reactions are one of the most important nonradiative decay processes for electronically excited molecules.1

\[ D + A \rightarrow D^* + A \rightarrow D^+ + A^- \] (1)

The photoexcited species may act as either the electron donor or acceptor resulting in either oxidative or reductive quenching of an excited state. An emergent theme in supramolecular photochemistry has been the enhancement of reactivity for a given reaction by the incorporation of a covalent or noncovalent linkage between subunits as illustrated by eq 2.

\[ D \rightarrow L + A \rightarrow D^* - L \rightarrow D^+ - L^- \] (2)

There are several literature examples which use a combination of the anthracene chromophore as a photoactive electron acceptor and an N,N-dimethylaniline (DMA) moiety as electron donor for studies of intramolecular PET. For example, the simple alkyl linked systems (1), as shown in Chart 1, have been investigated for their propensity toward intramolecular exciplex formation5 and the subsequent charge-transfer interactions of their excited states.6 More recently, Mataga et al.4 have investigated these systems using time-resolved spectroscopic techniques in the picosecond and femtosecond time domains. The magnitude of the electronic coupling between donor and acceptor was found to be strongly influenced by increasing the length of the alkyl chain linker, leading to an attenuation of the observed PET rate constants from \(10^{12}\) to \(10^{11}\) s\(^{-1}\) as \(n\) increased from 1 to 3. For the rigidly linked system (2) (Chart 1), emission from the chromophore is bathochromically shifted with increasing solvent polarity, behavior typically ascribed to an exciplex.5 However, the bicyclic bridge in this case hinders the large changes in molecular geometry normally requisite for exciplex formation. The dipole moment calculated for (2) in the first excited singlet state is greater than 20 D, suggesting complete charge separation occurs upon excitation and the observed emission results from radiative charge recombination. From the rise time of the emission (\(\sim 15\) ps) a corresponding PET rate constant, \(k_{\text{PET}}\), of \(10^{11}\) s\(^{-1}\) may be calculated.

Alternatives to these simple linkages such as the flexible alkylamino ‘tren’ ligand (3) appended with the 4-dimethylaminobenzyl (DMAB) and 9-anthracenylmethyl donor–acceptor pair have also been recently reported by Bruseghini et al., together with an analogous compound lacking the appended DMAB components.5 Under alkaline conditions, emission from the anthracene chromophore is reductively quenched via a PET mechanism involving free alkylamines as electron donors. This reaction is deactivated by protonation under acidic conditions or upon complexation with Zn(II). However, the fluorescence profile for the Zn(II) complex of (3) differed significantly to that of the control system lacking the DMAB moieties, due to the presence of an alternate PET quenching pathway, with DMAB acting as the electron donor. This pathway was largely deactivated by the addition of triphenylacetate, which axially coordinates to Zn(II) via the carboxylate group. Hence, the authors were able to ascribe a ‘through-space’ mechanism to...

the observed PET quenching reaction, which was blocked by intercalation of the anion.6

Herein, we describe the photophysical behavior of L3 (Chart 1), a rare example of a macrocyclic system with an appended photoactive chromophore and suitable electron donor, facilitating its use as a probe for the study of intramolecular PET. This compound is also the first example of a system whereby these two asymmetric components have been introduced via initial C-substitution of the cyclam core with pendant primary amino groups, which may be subsequently functionalized with ease. As a result, the anticipated coordination tendencies of the macrocycle will remain essentially unaffected by this synthetic modification, allowing facile complexation with a variety of first row transition-metal cations (such as Zn(II), vide infra) using well known cyclam chemistry.

Experimental Section

Synthesis. Synthetic procedures employed for the preparation of the parent L1 macrocycle in its free base form and the monosubstituted 9-anthracenylmethyl derivative, L2, have been previously described.7,8 Corresponding Zn(II) complexes were generated in situ by titration with 1.1 equiv of Zn(ClO4)2 6H2O. Unless otherwise stated, all other reagents were obtained commercially and used without further purification.

6-((Anthracen-9-yl-methyl)amino)-trans-6,13-dimethyl-13-((4-dimethylaminobenzyl)amino)-1,4,8,11-tetraazacyclotetradecane, L3. L1 (0.52 g, 2.0 mmol) was melted at 150 °C in a 50 mL round-bottomed flask and stirred. Solid 4-dimethylaminobenzaldehyde (0.30 g, 2.0 mmol) was added, and a stream of air was passed across the top of the reaction vessel to remove liberated water vapor. The reactants were stirred for ca. 30 min, during which time they solidified to give a toffee-like solid. In a separate flask, NaBH4 (0.23 g, 6.0 mmol) was dissolved in dry EtOH (25 mL), which was then added in portions to the crude product as it cooled. This solution was stirred for 2 h at room temperature, then H2O (200 mL) was added, and the resulting suspension was extracted with CH2Cl2 (3 x 75 mL). Removal of the solvent gave an oil, which was redissolved in an EtOH/H2O mixture (9:1, v/v, 200 mL), and HCl (1 M) was added until the pH of the resulting solution was 6.3. Na[CN-(BH3)] (0.38 g, 6.0 mmol) was added, resulting in precipitation of a white powder which was removed via filtration and subsequently identified by 1H NMR to be the cyanoborohydride salt of the symmetrically disubstituted bis(4-dimethylaminobenzyl) L1 adduct. To the filtrate was added anthracene-9-carbaldehyde (0.31 g, 2.0 mmol) which was dissolved separately in EtOH (50 mL), and the resulting solution was stirred at room temperature for 2 h while maintaining the pH at ca. 6.3 by the addition of aliquots of HCl (1 M) as required. This solution was then left to stir overnight to give a precipitate of the desired product as the cyanoborohydride salt [H2L3][CN(BH3)]. This was collected by vacuum filtration then converted to its free base form by suspending in NaOH (1 M, 200 mL) followed by extraction with CH2Cl2. The organic layer was dried over Na2SO4, and removal of the solvent gave a pale yellow solid which was recrystallized from a 1:1 mixture of CH2Cl2:CH3CN (v/v) to give a pale yellow solid which was filtered and washed with Et2O (0.37 g, 0.63 mmol, 31.4%). Elemental analysis: Found C, 71.97; H, 8.89; N, 16.39%. Calcd C, 72.08; H, 8.91; N, 16.34% for C36H51N7H2O. 1H NMR: (CDCl3) δ 1.11 (s, 3H, CH3), 1.40 (s, 3H, CH3), 2.1 (s br, 6H, NH), 2.4-2.9 (m, 16H, CH2-macrocyclic), 3.62 (s, 2H, N-CH2-DMA), 4.64 (s, 2H, N-CH2-Anth), 6.70 (d, 2H), 7.22 (d, 2H), 7.4-7.5 (m, 4H), 7.97 (d, 2H), 8.42 (s, 1H), 8.43 (d, 2H) ppm. 13C: (CDCl3) δ
23.01, 23.05, 38.1, 40.9, 45.6, 48.7, 48.9, 55.1, 55.9, 57.55, 57.63, 112.9, 124.5, 124.9, 125.8, 127.0, 129.0, 129.1, 129.5, 130.4, 131.7, 132.2, 149.8 ppm. X-ray quality crystals were obtained by slow evaporation of this product from a 1:1 (v/v) CH2Cl2:CH3CN solvent mixture.

Physical Methods. Nuclear magnetic resonance spectra were measured at 400.13 (1H) and 100.62 MHz (13C) on a Bruker AV400 spectrometer using a 1:1 CD3CN/CD2Cl2 (v/v) solvent mixture and referenced to the residual CH2CN solvent peak at 1.96 ppm vs TMS. Electronic absorption spectra were measured on a Perkin-Elmer Lambda 40 spectrophotometer using quartz cells. Steady-state emission and excitation spectra were collected on a Perkin-Elmer LS-50B spectrophotometer. Samples were purged with N2 prior to measurements, and cut off filters were employed to avoid detection of higher order excitation light. Electrochemical measurements were performed using a BAS100B/W potentiostat with a Pt wire auxiliary electrode, a Ag/AgNO3 (0.01 M in DMF) nonaqueous reference electrode, and a glassy carbon working electrode. All solutions utilized DMF as the solvent for enhanced solubility, were purged with N2 prior to measurements, and contained ca. 5 × 10−3 M analyte with 0.1 M Et4NClO4 as the supporting electrolyte. Measured potentials were referenced to the ferrocene-ferrocenium couple, which was used as an external standard.

Fluorescence lifetimes were determined by time-correlated single photon counting (TCSPC) measurements using an experimental setup similar to that previously described. An excitation wavelength of 395 nm was achieved using the Tsunami, Spectra-Physics laser (Tsunami, Spectra-Physics). The full width at half-maximum output of Kerr lens mode-locked Ti:Sapphire laser (Tsunami, Spectra-Physics) and has been described in detail previously. An excitation wavelength of 395 nm was achieved using a pulsed laser diode (Picoquant, LDH-P-C-400B). The average power at 20 MHz was 0.5 mW, and the pulse duration was about 65 ps. Solution concentrations were ~10−3 in analyte, which, if necessary, were further diluted to maintain an optical density of no more than 0.1 at the excitation wavelength, and samples were degassed thoroughly by purging with N2 prior to each measurement. The measured full width at half-maximum (fwhm) for the instrument response function (IRF) of this experimental setup was less than 200 ps. Observed fluorescence time profiles were analyzed by iterative reconvolution with the measured instrument response functions using a nonlinear least-squares fitting procedure.

The fluorescence upconversion setup was based on the commercially available FOG100 system (CDP, Laser & Scanning Systems) and has been described in detail previously. An excitation wavelength of 395 nm was achieved using the frequency doubled output of a Kerr lens mode-locked Ti:Sapphire laser (Tsunami, Spectra-Physics). The full width at half-maximum (fwhm) for the instrument response function (IRF) for this setup was ca. 210 fs. Fluorescence time profiles were analyzed using a nonlinear least-squares fitting procedure.

The experimental setup used to perform picosecond multiplex transient grating experiments has also been described in detail elsewhere. In this case, the excitation (pump pulse) was achieved with the third harmonic output at 355 nm of an active/passive mode-locked Q-switched Nd:YAG laser with a single amplification stage (Continuum, PY61-10). The duration of the pulses was about 25 ps, and the pump intensity on the sample was on the order of 2 mJ/cm². The time resolution of this experimental setup was ca. 30 ps.

Molecular modeling of [ZnL3]2+ was performed with MO-MEC97 using previously reported force field parameters to evaluate likely solution conformations. Drawings of modeled structures were produced with RASMOL.

Crystallography. Cell constants were determined by a least-squares fit to the setting parameters of 25 independent reflections measured on an Enraf-Nonius CAD4 four circle diffractometer employing graphite monochromated Mo Kα radiation (0.71073 Å) and operating in the φ-2θ scan mode. Data reduction and empirical absorption corrections (φ-scans) were performed with the WINGX package. The structure was solved by direct methods with SHELXS and refined by full-matrix least-squares analysis with SHELXL. The drawing of the molecule was produced with ORTEP-3.

Crystal Data. 6-(19-Anthracenylmethyl)amino)-trans-6,13-dimethyl-13-((4-dimethylamino)benzyl)amino)-1,4,8,11-tetrazaaclotetradecane, C36H51N7, 581.84 g mol⁻¹, monoclinic, a = 9.2709(9), b = 32.4313(3), c = 11.6978(2) Å, β = 110.714(7)°, V = 3289.87(7) Å³, T = 293 K, space group P21/c (No. 14, variant of P21/c), Z = 4, μ(Mo Kα) = 0.71 cm⁻¹, 6136 reflections measured, 5758 unique (Rint = 0.1630) which were used in all calculations, R1 = 0.0627 (for obs. data, I > 2σ(I), wR2 = 0.2400 (all data).

Results

X-ray Crystallography. Crystals of L3 suitable for structural characterization were obtained, and a view of the molecule is shown in Figure 1. The appended 4-dimethylaminobenzyl (DMAB) and 9-anthracenylmethyl groups are essentially planar, with a maximum deviation apparent for C31 of 0.015 Å in the latter. The nitrogen atom of the DMAB moiety is sp² hybridized, indicated by the terminal H3C–N−phenyl and H3C–N–CH3 angles, which are ca. 121.9°, 120.0°, and 118.0°. As such, the lone pair of N7 is delocalized throughout the π system, and the terminal phenyl-N7 bond length (1.36 Å) is indicative of a bond order greater than one. The alkyl C–C and C–N bond lengths of the macrocyclic linker are typical, and the substituted propane diamine sections form a pseudochair configuration if H-bonds involving the adjacent secondary amines are included (e.g. N2–H2⋯N3 2.24 Å and N4–H4⋯N1 2.21 Å). Ancillary H-bonding interactions between adjacent macrocyclic secondary amino groups (e.g. N2–H2⋯N1 2.45 Å and N4–H4⋯N3 2.46 Å) and the exocyclic amine protons with endocyclic amine lone pairs are...
also evident (e.g. N6−H6⋯N2 2.45 Å and N5−H5⋯N4 2.46 Å). No other close contacts indicating intra- or intermolecular interactions were observed.

Electrochemistry. Electrochemical measurements were performed by cyclic voltammetry for L 3 and its Zn(II) complex utilizing DMF as the solvent with the resulting voltammograms as shown in Figure 2. For L 3, a single electron reversible wave was observed in the oxidative sweep at a potential of −2380 mV vs Fe 2+/3+, which was assigned to electrochemical generation of the anthracene radical monoanion and compares well to previously reported values. In the oxidative sweep, very broad irreversible waves, assigned to amine oxidation processes, were observed with a potential range from +300 mV to +1000 mV. As a consequence, the wave corresponding to electrochemical oxidation of the appended 4-dimethylaminobenzyl moiety was obscured compared to the analogous process for the anthracene radical monoanion and compares well to previously reported values. In the oxidative sweep, very broad irreversible waves, assigned to amine oxidation processes, were observed with a potential range from +300 mV to +1000 mV. As a consequence, the wave corresponding to electrochemical oxidation of the appended 4-dimethylaminobenzyl moiety was obscured compared to the analogous process for the anthracene radical monoanion and compares well to previously reported values.

Upon complexation with Zn(II), the amine oxidation potentials are anodically shifted, as evident from an irreversible wave at ca. +1000 mV. As a result, for [ZnL 3 ] 2+, electrochemical generation of the radical cation for the appended 4-dimethylaminobenzyl moiety is more readily apparent as an irreversible wave at ca. +430 mV. The electrochemical response for the Zn(II) complex in the reductive sweep was complicated by the concomitant wave at ca. −1000 mV (data not shown). As a consequence, the redox potentials for electrochemical generation of the anthracene radical anion for the Zn(II) complex could not be obtained.

Steady-State Photophysical Measurements. Electronic absorption spectra of the free ligand, L 3, and the corresponding Zn(II) complex were measured in CH 3 CN solution and are essentially indistinguishable. The spectrum of the latter is shown in Figure 3, together with the electronic spectra of the monosubstituted [ZnL 2 ] 2+ analogue. For both complexes, the spectra are dominated by intense absorptions in the UV region. By reference to the parent chromophore, the sharp peak at 254 nm may be assigned to the S 0 → S 1 transition of the anthracene chromophore, while the S 0 → S 2 transition for this chromophore is evident at lower energy as a vibronic progression with an origin at ca. 385 nm and additional peaks separated by ca. 1420 cm −1. The S 0 → S 2 band of the anthracene chromophore is only weakly electric dipole allowed and was not observed. For the 4-dimethylaminobenzyl chromophore, the S 0 → S 2 transition is masked by the anthracene S 0 → S 1 transition yet is manifest by a significant broadening of the latter peak on the low energy side at ca. 270 nm when compared to the corresponding absorption spectrum for the monosubstituted [ZnL 2 ] 2+ analogue (Figure 3). A second broad band is evident at ca. 310 nm, overlapping the anthracene S 0 → S 1 transition, which may be assigned to the 4-dimethylaminobenzyl S 0 → S 1 band. The bands for this chromophore are particularly evident in the difference spectrum between [ZnL 3 ] 2+ and [ZnL 2 ] 2+ which is shown as an inset of Figure 3. This corrected difference spectrum also reveals a third band at ca. 198 nm and is in agreement with the reported spectra for para-substituted N,N-dimethylaniline derivatives.

The emission spectrum of the free ligand, L 3, in its free base form, was characteristically weak due to significant PET quenching, with both the appended 4-dimethylaminobenzyl group and the macrocyclic amine lone pairs capable of acting as electron donors. By contrast, the emission spectrum of [ZnL 3 ] 2+ (λ ex = 365 nm), as shown in Figure 4, is characteristic of the appended anthracene chromophore, with an origin at ca. 390 nm, a maximum intensity at ca. 413 nm, and several other peaks of a Franck Condon vibrational progression clearly observed. The corresponding excitation spectrum (λ em = 413 nm) was found to be essentially identical to that of the monosubstituted [ZnL 2 ] 2+ complex. Notably, the fluorescence quantum yield of [ZnL 3 ] 2+ , as determined by the optically dilute method by comparison to the parent chromophore, was Φ F = 0.14 which is slightly diminished compared to that reported previously for [ZnL 2 ] 2+ of Φ F = 0.19.

Hence, additional steady-state emission measurements were performed with the [ZnL 2 ] 2+ complex in the presence of N,N-dimethylaniline (DMA) to assess the propensity for quenching of anthracene fluorescence by the intermolecular reaction.

\[
[Zn(L 3 ) 2 ]^{2+} + \text{DMA} \rightarrow [Zn(L 3 )^{(+)−}]^{2+} + \text{DMA}^{(+)−}
\]  

The resulting emission spectra in the presence of increasing DMA concentrations are shown in Figure 5 where a decrease in the anthracene fluorescence intensity with increasing quencher concentration is clearly demonstrated. Also shown as an inset is the corresponding Stern−Volmer plot of I 0 /I F vs [DMA], where I 0 and I F represent the fluorescence intensity in the presence and absence of quencher, respectively. This data set displayed a pronounced upward curvature at high concentrations of quencher, indicative of both dynamic and static quenching effects. Behavior of this type may be due to a ground-state association of [ZnL 2 ] 2+ with the DMA quencher or, alternately, due to the so-called transient effect, whereby a proportion of the quencher is in sufficient proximity for PET quenching to occur at the instant of excitation. In the present case, since there was no observable change to the electronic spectrum of
the anthracene chromophore in the presence of DMA to suggest a ground-state association, the data were fit to the latter model using an appropriately modified nonlinear form of the Stern–Volmer equation.

\[
\frac{I_F}{I_F^0} = 1 + K_{sv}[Q] \exp(\gamma VN_A[Q])
\]  

where \(I_F^0\) and \(I_F\) represent the fluorescence intensity in the absence and presence of a given quencher concentration, [Q], respectively, \(N_A\) is Avogadro’s number, and \(V\) is the volume (m\(^3\)) around the fluorophore wherein quenching occurs with unit efficiency (\(\gamma = 1\)). The resulting best fit values for \(K_{sv}\) and \(\gamma V\) were 39.9 ± 0.99 M\(^{-1}\) and 5.66 ± 0.47 \(\times 10^{-24}\) m\(^3\) respectively.

**Time-Resolved Photophysical Measurements.** Time-resolved fluorescence decay profiles for L\(^3\) and the corresponding Zn(II) complex generated in situ were measured by the TCSPC technique in a 1:1 (v/v) mixture of CH\(_3\)CN and toluene, with resulting decay parameters as summarized in Table 1. Corresponding parameters for L\(^2\) measured under identical conditions are also shown. The decay profiles of both ligands were nonexponential, requiring a triple exponential function to accurately reflect the data. Indeed, the fastest of these decay processes was less than the time resolution of the TCSPC setup, which necessitated further characterization using the shorter time scale fluorescence upconversion (FU) technique. The resulting FU decay curves (Supporting Information, Figure S1) may, in principle, be reproduced with a biexponential function that plateaus to a nonzero value. However, from TCSPC measurements, we know that this plateau arises due to the presence of the slower decaying components. Hence, the decays were fit to a four exponential function with two lifetimes fixed to the values obtained from TCSPC measurement, and the resulting fit parameters are summarized in Table 2.

In addition to characterizing the temporal profile, the excited-state population dynamics of L\(^3\) and its corresponding Zn(II) complex were also assessed using the transient grating (TG) technique. As discussed in detail elsewhere, these spectra are very similar to transient absorption spectra, the main difference being that the transient grating intensity is always positive. As shown in Figure 6(a), the TG spectra of L\(^3\) consist mainly of a band at 600 nm with a broad shoulder at ca. 700 nm. The former band at 600 nm can be assigned to \(S_1 \rightarrow S_0\) transitions of the anthracene chromophore, in accordance with

*Fixed to values from TCSPC measurements in the same solvent system.

**Figure 4.** Emission and excitation spectra of [ZnL\(^3\)]\(^{2+}\) in CH\(_3\)CN at 298 K.

**Figure 5.** Decreases in [ZnL\(^2\)]\(^{2+}\) fluorescence due to bimolecular PET quenching (see eq 3) with increasing dimethylaniline (DMA) concentration in CH\(_3\)CN at 298 K. Inset: Stern–Volmer plot of \(I_F^0/I_F\) at 413 nm with increasing [DMA] and least-squares fit (solid line) to eq 4.

**Figure 6.** (a) Transient grating spectra of L\(^3\) in 1:1 (v/v) CH\(_3\)CN:toluene at 355 nm excitation (the 532 nm spike is due to the second harmonic of Nd:YAG laser pulses) and (b) time evolution of the square root of the TG intensity at 600 nm (\(S_1 \rightarrow S_0\)).
previously reported spectra. 29,30 The decay kinetics of this band obtained from the time dependence of the square root of the TG signal (see Figure 6(b)) were consistent with the lifetimes of 9.3 and 140 ps, obtained by TCSPC and fluorescence upconversion (FU) measurements in the same solvent system. The shoulder at ca. 700 nm may be similarly assigned to the anthracene radical anion.31 This band is quite weak and displays decay kinetics that are more rapid than the 600 nm band, indicating the subsequent charge recombination (back electron transfer) process is faster than the initial photoinduced electron transfer, resulting in only a small population of charge separated compounds. Upon complexation to Zn(II), the PET reaction involving macrocyclic amine donors is deactivated, and the corresponding TG spectra (Figure 7(a)) display only a single band at 600 nm ascribed to S1 \( \rightarrow \) S0 of the anthracene chromophore, the decay kinetics of which were satisfactorily reproduced by a single-exponential decay with a 4.1 ns lifetime as determined by TCSPC measurements. More importantly, the TG spectra for [ZnL3]2+ showed no evidence of an anthracene radical anion absorption band.

Figure 7. (a) Transient grating spectra of [ZnL3]2+ in 1:1 (v/v) CH3CN:toluene at 355 nm excitation (the 532 nm spike is due to the second harmonic of Nd:YAG laser pulses) and (b) time evolution of the square root of the TG intensity at 600 nm (S1 \( \rightarrow \) S0).

Time-resolved TG measurements were also performed for the intermolecular PET reaction between [ZnL2]+ and N,N-dimethylaniline (eq 3), the results of which are shown in Figure 8. In this case, both the reactant, [Zn(L2)*]+, and product, [Zn(L2)-]+, of the intermolecular PET reaction are evident. The former is apparent as the band at 600 nm assigned to S1 \( \rightarrow \) S0 of the anthracene chromophore, the decay kinetics of which were satisfactorily reproduced by a single-exponential decay with a 4.1 ns lifetime as determined by TCSPC measurements. More importantly, the TG spectra for [ZnL2]2+ showed no evidence of an anthracene radical anion absorption band.

Figure 8. (a) Transient grating spectra of [ZnL2]2+ + 0.1 M DMA in 1:1 (v/v) CH3CN:toluene at 355 nm excitation (the 532 nm spike is due to the second harmonic of Nd:YAG laser pulses) and (b) time evolution of the square root of the TG intensity at 600 nm (S1 \( \rightarrow \) S0) and 750 nm (• Anth).
bonding pattern observed structurally for L$_3$ provides a cavity ideally suited for binding transition-metal ions such as Zn(II).

Upon complexation, a single predominant isomer of [ZnL$_3$]$^{2+}$ is formed in solution, as evidence from $^1$H NMR titrations of bonding pattern observed structurally for L$_3$ provides a cavity ideally suited for binding transition-metal ions such as Zn(II).

Upon complexation with Zn(II), the decay kinetics of L$_3$ are characterized by a single exponential decay profile, with dynamic features spanning several orders of magnitude in time scale. Notably, for L$_3$, the presence of the appended DMAB group provides an additional donor group compared to L$_2$. This influence of the appended DMAB in comparison to L$_2$ is expressed through several factors, including the observation of an anthracene radical anion absorption using transient methods (Figures 6 and 8). Corresponding time-resolved measurements for L$_3$ also revealed a multiexponential decay profile, with dynamic features spanning several orders of magnitude in time scale.

The fluorescence decay curves collected for [ZnL$_3$]$^{2+}$ in a 1:1 (v/v) CH$_3$CN:toluene solvent mixture yielded an apparent $K_{sv}$ of 39.9 ± 0.99 M$^{-1}$, which, using the equation

$$K_{sv} = k_{q} \tau_{o}$$

and a $\tau_0$ value of 2.21 ± 0.05 ns as previously reported, yields the lifetime of [ZnL$_3$]$^{2+}$ in CH$_3$CN solution, corresponding to a quenching rate constant, $k_{q}$, of 1.81 ± 0.09 × 10$^{10}$ M$^{-1}$ s$^{-1}$. The corresponding diffusional rate constant, $k_{diff}$, for CH$_3$CN at 298 K is calculated to be 1.74 × 10$^{10}$ M$^{-1}$ s$^{-1}$. Hence, the intermolecular PET quenching reaction shown in eq 3 may be considered to be diffusion limited.

The fluorescence decay curves collected for [ZnL$_3$]$^{2+}$ in a 1:1 (v/v) CH$_3$CN:toluene solvent mixture yielded a lifetime of 4.1 ns, which is comparable to that observed for [ZnL$_2$]$^{2+}$ in the same solvent system. However, if the slightly diminished lifetime observed for [ZnL$_3$]$^{2+}$ is taken as indirect evidence of a PET quenching effect, involving the appended DMAB moiety as an electron donor, and it is assumed the other bands which could be assigned to anthracene radical anion structure should also hold for [ZnL$_3$]$^{2+}$. Importantly, however, for [ZnL$_3$]$^{2+}$, the appended DMAB group remains as a potential PET electron donor.

Thermodynamically, the PET reaction between the appended anthracene and DMAB moieties may be estimated using the general form of the Rehm–Weller equation

$$\Delta G^{\circ} = E^{\circ} - E^{\circ}(A/A^-) - \Delta E_{00}$$

where $E^{\circ}(D+/D)$ is the standard redox potential for oxidation of the donor, $E^{\circ}(A/A^-)$ is the standard redox potential for reduction of the acceptor, and $\Delta E_{00}$ is the spectroscopic zero point energy of the state for the photoactive component (in eV) above the ground electronic state. In the present case, an analysis of this type was complicated by electrodeposition of elemental zinc on the electrode surface, which made it impossible to accurately determine the An^- redox potential in the complex using cyclic voltammetry. Nonetheless, substituting the value obtained for the free ligand, the driving force for PET was estimated to be ca. $-0.43$ eV, in agreement with similar calculations from the literature.

Transient grating results for [ZnL$_3$]$^{2+}$, however, did not reveal any bands which could be assigned to anthracene radical anion formation by a PET reaction with the 4-dimethylaminobenzyl group acting as electron donor. This may be contrasted with the steady state and transient grating results from the intermolecular PET reaction (eq 3) of [ZnL$_2$]$^{2+}$, where observation of a significant fluorescence quenching effect due to addition of N,N-dimethylaniline and the detectable anthracene radical anion spectrum were clearly evident (see Figures 5 and 8). Corresponding Stern–Volmer analysis of the steady-state data yielded an apparent $K_{sv}$ of 39.9 ± 0.99 M$^{-1}$, which, using the equation

$$K_{sv} = k_{q} \tau_{o}$$

and a $\tau_0$ value of 2.21 ± 0.05 ns as previously reported, yields the lifetime of [ZnL$_3$]$^{2+}$ in CH$_3$CN solution, corresponding to a quenching rate constant, $k_{q}$, of 1.81 ± 0.09 × 10$^{10}$ M$^{-1}$ s$^{-1}$. The corresponding diffusional rate constant, $k_{diff}$, for CH$_3$CN at 298 K is calculated to be 1.74 × 10$^{10}$ M$^{-1}$ s$^{-1}$. Hence, the intermolecular PET quenching reaction shown in eq 3 may be considered to be diffusion limited.

The fluorescence decay curves collected for [ZnL$_3$]$^{2+}$ in a 1:1 (v/v) CH$_3$CN:toluene solvent mixture yielded a lifetime of 4.1 ns, which is comparable to that observed for [ZnL$_2$]$^{2+}$ in the same solvent system. Previous work, which utilized the parent L₁ macrocycle as a bridge between appended napthalene and anthracene chromophores to study intramolecular electronic energy transfer (EET), has ascribed the electronic coupling in that case primarily to a ‘through space’ Coulombic interaction, with a negligible ‘through-bond’ pathway. Since the macrocyclic linker is identical in this case, a similar situation will apply for the PET process under consideration here. In the absence of an effective ‘through-bond’ pathway, intramolecular PET must proceed via a ‘through-space’ mechanism. To provide structural details of the separation between the 4-dimethylaminobenzyl electron donor and anthracene acceptor in the [ZnL₂]⁻ complex, molecular modeling calculations were performed for the complex in the α-trans-II N-based isotemic form. Hence, for the 9-anthracenemethyl chromophore oriented with an axial disposition, there exist 4 local minima, and, similarly, for the 4-dimethylaminobenzyl moiety, which has local C₂ᵥ symmetry, a total of 6 rotational minima are evident. In combination, a total of 48 combinations were modeled accounting for both ‘syn’ and ‘anti’ conformers. The resulting strain energy minimized structures were Boltzmann weighted to account for the flexibility of the appended chromophores using the equation:

\[ p(i) = \exp\left(-\frac{E_i}{kT}\right) \sum_i \exp\left(-\frac{E_i}{kT}\right) \]  

where \( E_i \) is the minimized strain energy of the \( i \)th conformer, \( k \) is the Boltzmann constant, and \( T \) is the temperature (298 K). The resulting probability distribution of intramolecular separation, \( R \), is shown in Figure 9. In this case, \( R \) was defined as the distance between the aromatic carbon atom directly bound to the Me₂N⁻ group of the 4-dimethylaminobenzyl moiety (approximately equivalent to the center of mass) and the center of the anthracene aromatic ring system. As shown in Figure 9, the majority of modeled conformers have intramolecular separations that are in excess of 10 Å, well in excess of the typical van der Waals radii for the donor and acceptor components.

At this separation, the value of \( k_{PET} \) via a ‘through-space’ mechanism should be negligibly small, since the electron density of the donor and acceptor orbitals decreases exponentially with increasing radius. However, in a recent theoretical study of intramolecular PET between anthracene and dimethylsiloxane by Ando, PET rate constants were calculated as a function of the center of mass distance between the interacting donor acceptor pair and were found to rapidly increase with an apparent maximum of \( \sim 10^{10} \text{s}^{-1} \) at a separation of ca. 5 Å. Moreover, the apparent separation yielding a rate constant of \( \sim 10^7 \text{s}^{-1} \) was ca. 8 Å, which is similar to the modeled ‘closest approach’ conformer shown in Figure 9. Thus, for the [ZnL₂]⁻ complex, it is proposed that, while on the whole very efficient, PET quenching of the anthracene excited state may occur when the fluorophore and electron donor are within sufficiently close proximity (\( \sim 8-9 \) Å) to allow a ‘through-space’ PET reaction. Unfortunately, other than the slightly diminished fluorescence lifetime, direct evidence for this process is lacking.

Conclusions

Experimental techniques required for the synthesis of asymmetrically disubstituted L₁ derivatives are now well developed, and, with the structural characterization of L₁ reported herein, the parent macrocycle has again proven itself amenable to further functionalization with a variety of differing functional groups. Unlike previous examples of this type, however, the anticipated enhancement of PET activity for [ZnL₁]₂⁻ is notably absent. Indeed, by comparison to the intermolecular behavior of [ZnL₁]⁻ and DMA, PET activity is in fact diminished, no doubt due to the lack of an effective ‘through-bond’ electronic coupling pathway. Furthermore, it has become apparent the trans disposition of the pendant exocyclic amine attachment points and the bulk of the macrocyclic complex used as a bridge between the photoactive components inhibits their close approach in order to interact ‘through-space’. Rather, the linker used or L₁ can be envisaged as a ‘molecular curtain’ that screens the two groups and prevents their interaction. Hence, the importance of the bridge in influencing intramolecular PET dynamics and photophysical behavior has been illustrated.
