Modelling Lorenz Curves: robust and semi-parametric issues

COWELL, Frank, VICTORIA-FESER, Maria-Pia

Abstract

Modelling Lorenz curves (LC) for stochastic dominance comparisons is central to the analysis of income distributions. It is conventional to use non-parametric statistics based on empirical income cumulants which are used in the construction of LC and other related second-order dominance criteria. However, although attractive because of its simplicity and its apparent flexibility, this approach suffers from important drawbacks. While no assumptions need to be made regarding the datagenerating process (income distribution model), the empirical LC can be very sensitive to data particularities, especially in the upper tail of the distribution. This robustness problem can lead in practice to “wrong” interpretation of dominance orders. A possible remedy for this problem is the use of parametric or semi-parametric models for the data-generating process and robust estimators to obtain parameter estimates. In this paper, we focus on the robust estimation of semi-parametric LC and investigate issues such as sensitivity of LC estimators to data contamination (Cowell and Victoria-Feser, 2002), trimmed LC (Cowell and […]

Modelling Lorenz Curves: robust and semi-parametric issues

Frank A. Cowell† and Maria-Pia Victoria-Feser‡

Abstract

Modelling Lorenz curves (LC) for stochastic dominance comparisons is central to the analysis of income distributions. It is conventional to use non-parametric statistics based on empirical income cumulants which are used in the construction of LC and other related second-order dominance criteria. However, although attractive because of its simplicity and its apparent flexibility, this approach suffers from important drawbacks. While no assumptions need to be made regarding the data-generating process (income distribution model), the empirical LC can be very sensitive to data particularities, especially in the upper tail of the distribution. This robustness problem can lead in practice to “wrong” interpretation of dominance orders. A possible remedy for this problem is the use of parametric or semi-parametric models for the data-generating process and robust estimators to obtain parameter estimates. In this paper, we focus on the robust estimation of semi-parametric LC and investigate issues such as sensitivity of LC estimators to data contamination (Cowell and Victoria-Feser [2002]), trimmed LC (Cowell and Victoria-Feser [2006]), and inference for trimmed LC (Cowell and Victoria-Feser [2003]), robust semi-parametric estimation for LC (Cowell and Victoria-Feser [2007]), selection of optimal thresholds for (robust) semi-parametric modelling (Dupuis and Victoria-Feser [2006]), and use both simulations and real data to illustrate these points.

1 Introduction

The Lorenz curve is central to the analysis of income distributions, embodying fundamental intuition about inequality comparisons (Dagum (1985), Cowell and Victoria-Feser (2007)). Ranking theorems based on Lorenz dominance and the associated concept of stochastic dominance are fundamental to the theoretical welfare economics of distributions. But formal welfare propositions can only be satisfactorily invoked for empirical constructs if sample data can be taken as a reasonable representation of the underlying income distributions under consideration. In practice income-distribution data may be contaminated by recording errors, measurement errors and the like and, if the data cannot be purged of these, welfare conclusions drawn from the data can be seriously misleading. Indeed, it has been formally shown that Lorenz and stochastic dominance results are non-robust (Cowell and Victoria-Feser, 2002). This means that small amounts of data contamination in the wrong place can reverse unambiguous ranking orders: the “wrong place” usually means in the upper tail of the distribution. This is of particular interest in view of a burgeoning recent literature that has focused on empirical issues concerning the upper tail of both income distributions and wealth distributions (Atkinson (2004), Kopczuk and Saez (2004), Moriguchi and Saez (1991), Piketty (2001), Piketty and Saez (2003), Saez and Veall (2005)). So it is important to have an approach that enables one to control for the distortory effect of upper-tail contamination in a systematic fashion. This paper addresses the problem by introducing a robust method of estimating Lorenz curves and implementing stochastic-dominance criteria. To this end we have assembled some recent research on this issue, mainly drawing on the results of Cowell and Victoria-Feser (2007) and Cowell and Victoria-Feser (2006).

Our approach is organized as follows. We begin, in section 2, by setting out the formal background to the Lorenz curve and the estimation problems associated with extreme values. Section 3 develops the semi-parametric approach to modelling Lorenz curves and section 4 discusses the practical problem of parameter choice in implementing the method. Section 5 applies the method to UK data and section 6 concludes.

2 Background

We may set out the formal representation of the Lorenz Curve using the following simple framework. Let $\mathcal{F}$ be the set of all univariate probability distributions and $X$ be a random variable with probability distribution $F \in \mathcal{F}$ and support $\mathbb{R} \subseteq \mathbb{R}$. $F$ can be thought of as a parametric model $F_\theta$. We shall write statistics of any distribution $F \in \mathcal{F}$ as a functional $T(F)$; in particular we write the mean as $\mu(F) := \int x dF(x)$. A key distributional concept derived from $F$ is given by the $q^{th}$ cumulative functional $C : \mathcal{F} \times [0,1] \rightarrow \mathbb{R}$:

$$C(F;q) := \int_{\mathcal{X}} q(F;x) \cdot x dF(x) = c_q.$$  

(2.1)
where \( x := \inf X \) and

\[
Q(F; q) = \inf \{x \mid F(x) \geq q\} = x_q
\]

(2.2)
is the quantile functional. The importance of this concept is considerable in the practical analysis of income distributions: for a given \( F \in \mathcal{F} \), the graph of \( C(F, q) \) against \( q \) describes the generalized Lorenz curve (GLC); normalizing by the mean functional \( \mu(F) = C(F, 1) \) one has the Relative Lorenz curve (RLC) (Lorenz, 1905):

\[
L(F; q) := \frac{C(F; q)}{\mu(F)}
\]

(2.3)
The GLC and RLC are fundamental to a number of theorems drawing welfare-conclusions from income-distribution data and other types of data.

Now consider the problem of estimating Lorenz curves. There are broadly three approaches.

1. **Nonparametric methods.** Cumulative functionals can obviously be estimated by replacing \( F \) in (2.1) by the empirical distribution of a sample of incomes \( x_1, \ldots, x_n \)

\[
F^{(n)}(y) = \frac{1}{n} \sum_{i=1}^{n} \mathbb{I}(y \leq x_i)
\]

where \( \mathbb{I}(\cdot) \) is the indicator function. However, this can lead to misleading conclusions when it comes to comparing distributions in terms of their cumulative functionals when there is data contamination (Cowell and Victoria-Feser, 2002). One way of avoiding the potential bias induced by extreme data in the tails is to rely on the concept of trimmed Lorenz curves: basically, \( F \) in (2.1) is replaced by the trimmed distribution \( \tilde{F}_\alpha \) given by:

\[
\tilde{F}_\alpha(x) := \begin{cases} 
0 & \text{if } x < Q(F, \alpha) \\
\frac{F(x) - \alpha}{1 - \alpha} & \text{if } Q(F, \alpha) \leq x < Q(F, \overline{\alpha}) \\
1 & \text{if } x \geq Q(F, \overline{\alpha}) 
\end{cases}
\]

with \( \alpha + \overline{\alpha} = \alpha \). Using \( \tilde{F}_\alpha \) instead of \( F^{(n)} \) amounts to trimming the sample data below \( Q(F, \alpha) \) and above \( Q(F, \overline{\alpha}) \), and then compute empirical cumulants. The theoretical aspects are handled in Cowell and Victoria-Feser (2006).

2. **Parametric modelling.** Alternatively, one can estimate \( F \) using a model (a functional form) such as the one proposed by Dagum (1977). The parameters should obviously be estimated in a robust fashion (see e.g. Victoria-Feser and Ronchetti (1994), Victoria-Feser (1995)), but as has been discussed in Cowell.

\[\text{Other models can be found in Dagum (1980, 1983), McDonald (1984) and an excellent overview is provided by Kleiber and Kotz (2003).} \]
and Victoria-Feser (2007), a full parametric estimation forces the data into the mold of a functional form that may not be suitable for comparisons.

3. **Semi-parametric approach.** The problem that a single, tractable functional form may not be appropriate for the data motivates the use of an approach in which the data above a threshold $x_0$ are (robustly) fitted to a parametric distribution, while the rest of the data are treated nonparametrically. The semi parametric approach is of particular interest because of its *ad hoc* use in practical treatment of problems associated with the upper tails of distributions. For example a Pareto tail is sometimes fitted to data in cases where data are sparse in order to provide better estimates of upper tail probabilities or higher quantiles.

It is this third estimation method, the semiparametric approach, that forms the focus of the present paper.

### 3 Semi-parametric robust estimation of Lorenz curves

If the range of $X$ is bounded below – 0 is a typical value – the problems with contaminated data occur in the upper tail of the distribution (Cowell and Victoria-Feser 2002). A case can therefore be made for using parametric modelling only in the upper tail and estimating the parameter of the upper-tail model robustly. The rest of the distribution is estimated using the empirical distribution function. If no restriction is imposed on the range of the random variable of interest, then the results below can easily be extended accordingly.

Cowell and Victoria-Feser (2007) proposed an approach which is suitable for any parametric model for the upper tail of the distribution. They however choose a model that is of special relevance empirically, that is the Pareto distribution given by

$$F_{\theta}(x) = 1 - \left[ \frac{x}{x_0} \right]^{-\theta}, \quad x > x_0$$

(3.1)

with density $f(x; \theta) = \theta x^{-(\theta+1)}x_0^\theta$. The parameter of interest is $\theta$.

A semi-parametric approach will combine a non-parametric RLC for say the $(1-\alpha)%$ lower incomes and a parametric RLC based on the Pareto distribution for the $\alpha%$ upper incomes. Therefore $x_0$ is determined by the $1 - \alpha$ quantile $Q(F; 1 - \alpha)$ defined in (2.2). The method for a suitable choice of $x_0$ is given in section 4. The full semi-parametric distribution $\tilde{F}$ of the income variable $X$ is

$$\tilde{F}(x) = \begin{cases} F(x) & x \leq x_0 \\ F(x_0) + (1 - F(x_0))F_{\theta,x_0}(x) & x > x_0 \end{cases}$$

where $F$ could be in principle any suitable parametric distribution, but in our case will be estimated by the empirical distribution. With $x_0 = Q(F; 1 - \alpha)$, we have

\footnotesize

\[^2\] $\theta$ is assumed to be greater than 2 for the variance to exist.\normalsize
\[
\begin{align*}
\tilde{F}(x) &= \begin{cases} 
F(x) & x \leq Q(F; 1 - \alpha) \\
1 - \alpha \left[ \frac{x}{Q(F; 1 - \alpha)} \right]^{-\theta} & x > Q(F; 1 - \alpha)
\end{cases} 
\quad (3.2)
\end{align*}
\]

For \( x > Q(F; 1 - \alpha) \), the density \( \tilde{f} \) is
\[
\tilde{f}(x; \theta) = \alpha \theta Q(F; 1 - \alpha)^\theta x^{-\theta - 1}.
\]

In particular
\[
\tilde{f}(x_1 - \alpha; \theta) = \frac{\alpha \theta}{x_1 - \alpha}.
\]

The quantile functional is then obtained using (3.2) and is given by
\[
Q(\tilde{F}, q) = \begin{cases} 
Q(F, q) & q \leq 1 - \alpha \\
Q(F; 1 - \alpha) \left( \frac{1 - q}{\alpha} \right)^{-1/\theta} & q > 1 - \alpha
\end{cases}
\]

Hence the cumulative income functional defining the semi-parametric GLC becomes
\[
C(\tilde{F}; q) = \int \frac{Q(\tilde{F}, q)}{x} x \tilde{F}(x) 
\]

\[
= \begin{cases} 
\int \frac{Q(F, \theta)}{x} x F(x) & q \leq 1 - \alpha \\
\int \frac{Q(F; 1 - \alpha)}{x} x F(x) + \alpha \int \frac{Q(F; 1 - \alpha)}{x} \left( \frac{1 - q}{\alpha} \right)^{-1/\theta} x F \theta & q > 1 - \alpha
\end{cases}
\]

\[
= \begin{cases} 
\int \frac{Q(F, \theta)}{x} x F(x) & q \leq 1 - \alpha \\
\int \frac{Q(F; 1 - \alpha)}{x} x F(x) + \alpha \frac{\theta}{1 - \theta} Q(F; 1 - \alpha) \left[ \left( \frac{1 - q}{\alpha} \right)^{\theta/\theta' - 1} \right] & q > 1 - \alpha
\end{cases}
\]

where \( x := \inf X \). The mean of the semi-parametric distribution is given by:
\[
C(\tilde{F}; 1) = \int \frac{Q(F, 1 - \alpha)}{x} x F(x) - \alpha Q(F; 1 - \alpha) \frac{\theta}{1 - \theta}
\]

\[
= c_{1 - \alpha} - \alpha x_{1 - \alpha} \frac{\theta}{1 - \theta}
\]

\[
= \mu(\tilde{F})
\]

The semi-parametric RLC is simply
The cumulative income function (3.6) obviously needs to be estimated. The (unknown) distribution $F$ is replaced by the empirical distribution $F^{(n)}$ and an estimate for $\alpha$ will be discussed in Section 4. To estimate the Pareto model, hence $\theta$, for the upper tail of the distribution, one can use the maximum likelihood estimator (MLE). Unfortunately, the MLE for the Pareto model is known to be very sensitive to data contamination (Victoria-Feser and Ronchetti, 1994). This is also the case for other models such as Dagum (1977) model (see Victoria-Feser (1995)). Cowell and Victoria-Feser (2007) propose using a robust estimator in the class of $M$-estimators (Huber (1981)). For a sample of $n$ observations $x_i$, a general $M$-estimator is defined as the solution in $\theta$ of

$$\frac{1}{n} \sum_{i=1}^{k} \psi(x_i; \theta) = 0$$

with some (mild) conditions on the function $\psi$. This function is chosen so that the resulting estimator is consistent at the model $F_\theta$ and also that it is robust to slight model deviations (for a discussion, see e.g. Hampel et al. (1986)). The latter condition is satisfied if the $\psi$-function is bounded, which is the case for so-called weighted MLE (WMLE), i.e.

$$\frac{1}{n} \sum_{i=1}^{k} w(x_i; \theta) [s(x_i; \theta) - a(\theta)] = 0$$

where $w(x; \theta)$ is a weight function with value in $[0, 1]$ insuring the robustness of the estimator, $s(x; \theta) = \partial / \partial \theta \log f(x; \theta)$ is the score function and $a(\theta)$ is a consistency correction factor. Cowell and Victoria-Feser (2007) choose the optimal B-robust estimators (OBRE) (Hampel et al., 1986), a robust estimator with minimal asymptotic covariance matrix (see e.g. Cowell and Victoria-Feser (2007) for details).

The resulting semi-parametric GLC (and RLC) estimates are hence robust to data contamination. They are based on the Pareto model for the upper tail and robustness is sought against deviations from the Pareto model. If the Pareto model is believed not to be suitable, then it can be changed (like e.g. to a generalized version of it) but the method remains the same. Cowell and Victoria-Feser (2007) also provide the asymptotic covariances of the estimators for inference with semi-parametric GLC (and RLC) which can be used for robust welfare comparison.

In section 5, an example will illustrate the performance of robust semi-parametric estimators of RLC and GLC.

---

3 The correction factor does not need to be estimated simultaneously, see below.
4 Choosing $\alpha$

The choice of the proportion $\alpha$ of data in the upper tail to be fitted to the Pareto model, or equivalently the threshold $x_0$ above which the data are fitted to a Pareto model, is not a problem specific to income distribution analysis. It has attracted and still attracts the attention of researchers in domains such as finance, insurance, engineering, or environmental sciences. This problem falls within the general heading of extreme value distributions (for a general reference, see e.g. Embrechts et al. (1997)). To estimate the threshold, a compromise should be sought between bias and variance: choosing a threshold too close to the central data will cause bias in the Pareto model estimator since only the tail can be assumed to be Pareto distributed, and selecting too extreme a threshold will yield large variances for the estimator since it will be based on a small sample. A common practice is to use the Pareto quantile plot (see e.g. Beirlant et al. (1996)). Indeed, rearranging (3.1) one gets

$$\log \left( \frac{x}{x_0} \right) = - \frac{1}{\theta} \log \left( 1 - F_\theta(x) \right), \quad x > x_0$$  \hspace{1cm} (4.1)

showing that there is a linear relationship between the log of the $x > x_0$ and the log of the survival function. This relationship was actually found empirically by Pareto (1896) and led him to the construction of his model (see also Dagum (1983)). Let $x_{[i]}$, $i = 1, \ldots, k$, be the ordered largest $k$ observations, so that $x_{[i]} = Q(F^*_n; i/(k+1))$, with $F^*_n$ the empirical distribution of $x_{[i]}$. The empirical counterpart of (4.1) is the Pareto quantile plot

$$\log \left( \frac{Q(F^*_n; i/(k+1))}{x_0} \right) = - \frac{1}{\theta} \log \left( \frac{k+1-i}{k+1} \right), \quad i = 1, \ldots, k.$$  \hspace{1cm} (4.2)

Therefore, given a sample of $n$ income data $x_i, 1, \ldots, n$ and by letting $x_{[i]}$ denote the $i$th order statistic, the plot of $\log \left( x_{[i]} \right)$ versus $- \log \left( (n+1-i)/(n+1) \right)$, $i = 1, \ldots, n$ is the Pareto quantile plot that is used to detect graphically the quantile $x_{[i]}$ above which the Pareto relationship is valid, i.e. the point above which the plot yields a straight line. We note that there is a clear relationship between $x_0$ and $k$ in that

$$k = \sum_{i=1}^n t(x_{[i]} \geq x_0).$$

More formally, a general approach in determining $k$ is the minimization of an estimate of the asymptotic mean squared error (AMSE) of the estimator of $\theta$. If a classical estimator such as the MLE is chosen, then the determination of $k$ can be influenced by extreme data in the upper tail (see Dupuis and Victoria-Feser (2006)). Note that here extreme is used relatively to the Pareto model: if it is assumed to fit the upper tail, then extreme data represent deviations for this assumption that can appear in the Pareto quantile plot as data that do not fit the straight line.

In order to choose $k$, or equivalently $x_0$ in a robust fashion, Dupuis and Victoria-Feser (2006) use another criterion, namely a prediction error criterion that is estimated robustly (see also Ronchetti and Staudte (1994)), named the RC-criterion.
Let \( Y_i = \log (x_i^* / x_0) \), \( i = 1, \ldots, k \), \( \hat{Y}_i = -1 / \hat{\theta} \log [(i + 1) / (k + 1)] \), \( i = 1, \ldots, k \), where \( \hat{\theta} \) is an estimator of \( \theta \), and

\[
\hat{\sigma}^2 = \text{var}(Y_i) = \frac{1}{n} \sum_{j=1}^{i} \frac{1}{\theta^2 (k - i + j)^2}
\]

the (estimated) RC-criterion is given by

\[
C_R(x_0) = \frac{1}{n} \sum_{i=1}^{n} \hat{w}_i^2 \left( \frac{Y_i - \hat{Y}_i}{\hat{\sigma}_i} \right)^2 + \frac{2}{n} \sum_{i=1}^{n} \frac{1}{\hat{\sigma}_i^2} \text{cov} \left[ \hat{w}_i Y_i, \hat{w}_i \hat{Y}_i \right] - \frac{1}{n} \sum_{i=1}^{n} \frac{1}{\hat{\sigma}_i^2} \text{var} \left[ \hat{w}_i Y_i \right] \tag{4.3}
\]

where each \( \hat{w}_i, 0 \leq \hat{w}_i \leq 1 \), is the fitted weight of the \( i \)th observation, provided by a robust fit of the Pareto model, using a WMLE given in (3.9). For suitable estimates of \( \text{cov} \left[ \hat{w}_i Y_i, \hat{w}_i \hat{Y}_i \right] \) and \( \text{var} \left[ \hat{w}_i Y_i \right] \), see Dupuis and Victoria-Feser (2006). The effect of extreme observations on the calculation of \( C_R(x_0) \) is controlled by the weights \( \hat{w}_i \). The criterion is minimized over possible values for \( x_0 \). Obviously, at the minimum, we have that \( Y_i \approx \hat{Y}_i \), hence \( \log (x_i^* / x_0) \approx -1 / \hat{\theta} \log [(i + 1) / (k + 1)] \).

For the choice of the WMLE, Dupuis and Victoria-Feser (2006) propose an estimator which downweights observations that are “far” from the Pareto model in terms of the size of the residuals with respect to the Pareto regression model, i.e.

\[
w(x_i^*; \theta) = \begin{cases} 
1 & \text{if } |r_i| \leq c \\
n/|r_i| & \text{if } |r_i| > c
\end{cases} \tag{4.4}
\]

with \( r_i = (Y_i - \hat{Y}_i) / \hat{\sigma}_i \) and \( c \) is a constant regulating the amount of robustness (for more details, see Dupuis and Victoria-Feser (2006)).

In the following section, an empirical example will illustrate the method.

5 Data analysis

Let us put the semiparametric method into practice using a typical income distribution. The data for our illustration are for household disposable incomes in the UK, 1981 (\( n = 7470 \)).

A Pareto quantile plot of the data together with fitted regression lines are given in Figure 1. The fits are provided by WMLE estimates with residual weights (4.4) for two values of \( c \) as well as the classical MLE. The optimal values for \( x_0 \) are obtained using \( C_R(x_0) \) in which the weights \( \hat{w}_i \) and \( \hat{Y}_i \) are obtained using the different estimators. For the MLE, \( \hat{w}_i = 1, \forall i \). The fit for the MLE (and hence the corresponding optimal value for \( x_0 \)) are not adequate, probably because of a few very extreme observations.

\footnote{The data set is Households Below Average Income which, despite its name, actually provides a representative sample of households over the whole income range – see Department of Social Security (1992) for details.}
observations. Both robust fits seem on the other hand appropriate. For the latter, the
optimal value of $x_0$ corresponds to $k = 22$ selected upper incomes ($k = 32$ for the
MLE). Figure 2 shows observations above the robustly selected threshold $x_0 = 803.3$
and arrows indicate the downweighted observations. The striking feature is that not
only the largest observations are downweighted, but also the smallest.

To estimate the Pareto parameter, we hence choose $k = 22$. The value for the
MLE is $\hat{\theta} = 17.5$ (with standard error 3.73) and the one for the OBRE with $c = 2.5$
is $\hat{\theta} = 76.65$ (17.62). We use these two estimates to build estimated RLC (see (3.6)
and (3.7)). These curves (corresponding to the 0.5% top incomes) are presented in
Figure 3 together with the empirical RLC estimate. Even if it is small, one can see a
difference between the three estimates, in that the MLE follows the empirical RLC
up to roughly the 0.1% of the top distribution, while the OBRE leads to an estimated
RLC showing less inequality on the entire 0.5% top range.

\footnote{One can note that a different robust estimator is used to estimate the Pareto parameter. For the
choice of $k$ a WMLE based on residual weights is a reasonable choice, whereas the more efficient
robust estimator (OBRE) for the Pareto parameter given a value for $k$ is also a reasonable choice.}
Modelling Lorenz Curves: robust and semi-parametric issues

Figure 2: Pareto quantile plot of income data above robustly chosen threshold. Downweighted observations (with WMLE, $c = 1.25$) are identified.

Figure 3: RLC (top 0.5%) estimates (empirical and semi-parametric with MLE and OBRE with $c = 2$) of the UK income data
6 Conclusion

Using ranking criteria to compare distributions is of immense theoretical advantage and practical convenience. In welfare economics they provide a connection between the philosophical basis of welfare judgments and elementary statistical tools for describing distributions. In practical applications they suggest useful ways in which simple computational procedures may be used to draw inferences from collections of empirical distributions. However, since it has been shown that second order rankings are not robust to data contamination, especially in the upper tail of the distribution, it is important to provide the empirical researcher with computational devices which can be used to draw inferences about the properties of distributional comparisons in a robust fashion.

One way forward might be to estimate Lorenz curves through an appropriately specified parametric model and to estimate the model parameters robustly. However, this approach is too restrictive because tractable parametric models are unlikely to be sufficiently flexible to capture some of the essential nuances of Lorenz comparisons. For example, in order for Lorenz curves to be able to cross, a parametric model would usually need to incorporate at least three parameters, which itself may lead to serious estimation complications.

The method proposed here is a semi-parametric approach in that the upper tail of the distribution is robustly fitted using the Pareto model and a semi-parametric Lorenz curve is then built which combines non-parametric cumulative functionals and estimated ones. Simulated examples have proved not only that a few extreme data can reverse the ranking order, but also that the robust parametric Lorenz curve restores the initial ordering. Inference can be made for comparing two distributions even in the semi-parametric setting, by extending the general setting provided in Cowell and Victoria-Feser (2007). For variances too, a robust approach provides reasonable estimates when there is contamination. Note however, that inference has been developed for a fixed value for the proportion $\alpha$ of data in the upper tail, and when it is estimated as is done in this paper, inference that takes into account the variability of an estimator of $\alpha$ is still an open question.

Finally note that although we took the Pareto distribution as a suitable parametric model for the upper tail, and although we considered the (most common) case of a range of definition for the variable bounded below, our results can be extended to other models and to two-tail modelling in a relatively straightforward manner.
