Cloning entangled photons to scales one can see

SEKATSKI, Pavel, et al.

Abstract

By amplifying photonic qubits it is possible to produce states that contain enough photons to be seen with the human eye, potentially bringing quantum effects to macroscopic scales [P. Sekatski, N. Brunner, C. Branciard, N. Gisin, and C. Simon, Phys. Rev. Lett. 103, 113601 (2009)]. In this paper we theoretically study quantum states obtained by amplifying one side of an entangled photon pair with different types of optical cloning machines for photonic qubits. We propose a detection scheme that involves lossy threshold detectors (such as the human eye) on the amplified side and conventional photon detectors on the other side. We show that correlations obtained with such coarse-grained measurements prove the entanglement of the initial photon pair and do not prove the entanglement of the amplified state. We emphasize the importance of the detection loophole in Bell violation experiments by giving a simple preparation technique for separable states that violate a Bell inequality without closing this loophole. Finally, we analyze the genuine entanglement of the amplified states and its robustness to losses before, during, [...]

By amplifying photonic qubits it is possible to produce states that contain enough photons to be seen with the human eye, potentially bringing quantum effects to macroscopic scales [P. Sekatski, N. Brunner, C. Branciard, N. Gisin, and C. Simon, Phys. Rev. Lett. 103, 113601 (2009)]. In this paper we theoretically study quantum states obtained by amplifying one side of an entangled photon pair with different types of optical cloning machines for photonic qubits. We propose a detection scheme that involves lossy threshold detectors (such as the human eye) on the amplified side and conventional photon detectors on the other side. We show that correlations obtained with such coarse-grained measurements prove the entanglement of the initial photon pair and do not prove the entanglement of the amplified state. We emphasize the importance of the detection loophole in Bell violation experiments by giving a simple preparation technique for separable states that violate a Bell inequality without closing this loophole. Finally, we analyze the genuine entanglement of the amplified states and its robustness to losses before, during, and after amplification.

I. INTRODUCTION

The cloning of a photonic qubit is an intriguing subject, especially when the number of clones is so large that one can see them with the naked eye. Such a macroscopic photonic state is worth analyzing, especially when the initial qubit is entangled with a twin photon [1] as illustrated in Fig. 1. This is the main purpose of this article, though still at the theoretical level. Naively, one could think that if one has access to a number of clones, even of poor quality, then one could measure the state in which these clones are and infer the state of the initial qubit. This idea, applied to half of an Einstein-Podolsky-Rosen (EPR) entangled pair of photons, is the basis of the faster-than-light flash telegraph proposed by Herbert in the 1980s [2]. The no-cloning theorem was actually motivated by the impossibility of this flash telegraph [3–5]. Today it is known that optimal quantum cloning has a fidelity which is precisely at the limit of the flash telegraph: If one could clone qubits any better than allowed by quantum physics then one could use this process, together with entanglement, to signal at arbitrarily high speeds [6,7].

The reason why one cannot extract more information from the many clones obtained by optimal quantum cloning than from the original qubit is that the many clones are in a complex entangled state [8]. Indeed, would they be in a product state, then one could measure them individually and accumulate a lot of information from which the initial qubit state could indeed be inferred. But, actually, for any arbitrary number of clones, if optimal, their entangled state contains precisely the same information as the original qubit [8,9]. Hence, a large number of clones constitute a sort of macroscopic “qubit.” Note, however, that this macroscopic state is not a real qubit: It lives in a Hilbert space of a dimension much larger than two (the only exception is the optimal phase covariant cloner with precisely N output photons with zero loss). Nevertheless, we adopt the terminology macroscopic “qubit” as a shorthand for the macroscopic quantum state produced by cloning of a single-phonon qubit.

One of the fascinating aspects of a macroscopic photonic “qubit” is that one should be able to see it with the naked eye. What exactly can be inferred from such a direct observation of a “qubit” is the central issue of this paper. The eye is, to a good approximation, a seven-photon threshold detector preceded by about 90% loss between the pupil and the retina [10] (nature doesn’t always produce perfect optics [11]). In this article “to see” means to detect using two threshold detectors with postselection of the cases where one and only one detector went above the threshold.

This article addresses four main questions. First, can one see the entanglement that exists between the two initial photons, that is, can one see the micro-micro entanglement (see first line of Table I)? By seeing entanglement we mean to infer it from the correlations between the two subsystems where one is observed with lossy threshold detectors as shown in Fig. 1. Second, is there, in principle, any entanglement between the macroscopic “qubit” and the twin photon (line 2 of Table I)? Third, can one see any micro-macro entanglement between the macroscopic “qubit” and the twin photon (line 3 of Table I)? And finally, does the seen correlation violate a Bell inequality with postselection (last line of the table)?

But let us first consider the different kinds of cloners and the very different ways of realizing optimal quantum cloning (i.e., the columns of Table I). Universal cloning (first column), which clones all possible qubits with equal fidelity, can be realized with a simple optical amplifier (e.g., an erbium-doped fiber amplifier [12]). Universal cloning necessarily comes with additional quantum systems called anticlones; in the previously mentioned example the additional systems are the erbium ions. The clones and anticlones (e.g., photons and ions) are entangled, hence when one considers only the clones, one expects that their entanglement with the twin photon is reduced, as mentioned in Table I and quantified in Sec. VI. Phase covariant cloning (second column) that best clones all
obviously, this measure-and-prepare cloner (third column basis, one thus obtains universal or phase covariant clones the measurement result. When averaged over the measurement circle) and produce many qubits in the state corresponding to the clones then there is a much simpler way of obtaining many

\[ \frac{1}{\sqrt{n}} \] (ideally [scales as No] of the table) is not identical to the amplifier-based cloner. Indeed, when applied to one photonic qubit entangled with a twin photon, the measure-and-prepare cloner clearly breaks the entanglement. Interestingly, this is not the case for the amplifier-based cloners, as already mentioned. However, we shall see that the correlations observed with threshold detectors are almost identical whether one uses the measure-and-prepare cloner or an amplification-based cloner, hence it is clearly impossible to see micro-macro entanglement.

Next we come to the question whether one can see micro-macro entanglement. Entanglement is a concept defined within Hilbert space quantum physics: A quantum state is entangled if and only if it cannot be written as a product, but only as a sum of product states. Moreover, it is well known that all entanglement witnesses, except Bell inequalities, require assumptions on the dimension of the Hilbert space. Consequently, the question of can one see entanglement implicitly assumes standard quantum physics and a given Hilbert space [16]. In practice, if one considers the cloning machine as part of the measurement apparatus, then one studies the correlations between the two micro-micro photons. While, if one considers the cloning machine as part of the source, then one studies the correlation between the micro-macro photonic qubits. In the first case the Hilbert space dimension is clearly \( 2 \times 2 \); this case can thus be analyzed as usual and the use of cloners and threshold detectors with finite efficiency is similar to the case in which equally inefficient single-photon detectors are used (important, however, is that the efficiency has to be independent of the measurement settings). Accordingly, it is possible to see micro-micro entanglement. However, there is one big difference between the case of single-photon detectors and that of cloner + threshold detectors that we would like to emphasize. In the first case, the measurement setting is chosen before the signal is amplified to the classical level while in the latter case amplification happens before the choice of the measurement setting. This is not a mere detail, but a rather crucial point because in the latter case the amplified two-partite state has the symmetry (or at least a part of it, as will be clear later) of the initial photon pair state, which is obviously not the case in standard detection schemes. Furthermore, if the choice of the measurement basis is prior to the amplification the information carried by the macroscopic state is the answer to the asked question (just one bit in the binary case), while in our case the macroscopic state carries the answers to all the possible questions. Note that in the standard case if Alice and Bob do not get the information about what setting had been used, then in most cases their state is completely unsuitable for any

\[ |\psi\rangle = \frac{1}{\sqrt{2}} (|0\rangle + |1\rangle) \]

FIG. 1. (Color online) A source produces two entangled photons. The left one is measured using single-photon detectors (SPD). The right-hand side one is first amplified (\( \chi \)) and the detection is made by two “eyes” modeled as losses and two threshold detectors.

1If the observed correlations are local in the sense that they violate no Bell inequality, then there exists an underlying local model, with a local variable \( \lambda \) that reproduces these correlations. As a result any particular local configuration \( \lambda \) can be implemented as a produced state \( |\psi\rangle \) of a quantum system if we allow the dimension of its Hilbert space to be arbitrarily large (potentially reproducing all the classical physics).

2This difference is easier to grasp if we divide the physical process into three stages: the preparation stage (a two photon state), the transformation stage (amplification of Alice’s part), and the observation stage.
further analysis (for example, if the macroscopic outcomes of the measurement are red or green lights) while in some exotic cases, which deserve special attention, the state is similar to the outcome of the measure-and-prepare cloner.

In the micro-macro case, the dimension of the relevant Hilbert spaces is more tricky. It depends on the kind of cloner and on the presence of losses. Generally, if there are $N$ photons, the state is a superposition of symmetric states with $n$ photons polarized vertically and $N-n$ polarized horizontally with $n = 0, \ldots, N$, hence there are $N+1$ orthogonal states. In brief, in the micro-macro case, the Hilbert space dimension is much larger than two and detecting entanglement should be much harder, as we confirm in Sec. VI. Actually, as already mentioned, it is impossible to detect micro-macro entanglement with threshold detectors (i.e., it is impossible to see micro-macro entanglement).

Nonlocality, that is, the violation of a Bell inequality, is a concept that, contrary to entanglement, goes beyond quantum physics: Correlations are nonlocal if and only if they cannot be reproduced by local variables. Hence, the locality or nonlocality of seen correlations has nothing to do with the quantum stuff measured, it is only a characteristic of the classical data collected by the measurements. According to quantum physics, nonlocal correlations can only be obtained when measuring entangled states. Hence, the observation of nonlocal correlation is a signature that the measured quantum state was entangled, irrespective of any Hilbert dimension criteria. From this and the conclusion of the previous paragraph one can already conclude that it is impossible to see nonlocal correlations. Moreover, since the study of nonlocality goes beyond quantum physics, one has to be careful with finite efficient detection: The nondetected events could open the possibility to describe the experiment by local variables. This is the famous detection loophole. This loophole is often misconstrued as esoteric, but we shall see that if not taken into account one can easily come to the wrong conclusions. Indeed, we shall see that if one merely ignores nondetected events one can violate the Clauser-Horne-Shimony-Holt (CHSH)-Bell inequality even with an entanglement-breaking cloner and threshold detectors, see Sec. V.

II. GENERAL SCENARIO

In a previous article [1] we discussed the possibility of designing quantum experiments using the naked eye as detectors. We showed that this can be done with a cloning machine, which amplifies the state to visible levels before the choice of measurement basis is made. The setup of the proposed Bell experiment is shown in Fig. 1: First, an entangled photon pair singlet state $|\psi^-(a,b)⟩ = \frac{1}{\sqrt{2}}[a^\dagger b^\dagger − a^\dagger b^\dagger]|0⟩$ is produced by parametric down-conversion where $a^\dagger,a^\dagger, b^\dagger,b^\dagger$ are the creation operators for two orthogonal polarizations in the spatial mode $a(b)$. One photon is measured, in any desired basis, with standard single-photon detectors, which for simplicity we assume to have negligible noise. The other photon is amplified (cloned) and the two desired orthogonal polarization components are measured with human eyes. The choice of the basis for the measurement is done by adjusting the linear optical elements before the polarizing beam splitter separates the two polarizations, of course with linear optics it is, in principle, possible to achieve any rotation of the Poincaré sphere. We consider a measurement to be conclusive if one and only one eye sees a signal. This kind of postselection allows one to violate the CHSH-Bell inequality using any of the three types of amplification presented in the Introduction. In this section we will answer the following question: Does the entanglement present in the initial state survive the amplification process? What can one deduce from the measurement statistics of this experiment? We emphasize that our goal here is to discuss a particular physical situation and not the most general case.

III. TYPES OF CLONING MACHINES

In this section we review the three kinds of cloning machines considered in this article: the universal, phase covariant, and measure-and-prepare cloning machines. For each one we introduce the mathematics describing the amplification of an input qubit to a large number of output qubits.

A. Universal cloning machine

A universal quantum cloning machine (UCM) is a device that clones all qubits on the Poincaré sphere equally well. In the case of photonic polarization qubits, such a device can be experimentally achieved by a type II down-conversion, seeded by the qubit (photon) to be cloned. The clones will be produced in the “signal” mode (i.e., the mode excited by the input photon). The photons in the idler mode, called the anticlones, are disregarded. In fact, any phase invariant amplifier, such as an erbium-doped fiber amplifier (EDFA), can be viewed as a UCM. It is to be noted that the transformation implemented by a UCM is not unitary, as the information carried by the anticlones is discarded.

The interaction Hamiltonian for an optimal universal quantum cloning machine can be written as [17]

$$H = i\chi(a^\dagger c^\dagger − a^\dagger c^\dagger) + \text{H.c.},$$

where $a$ is the input mode to be cloned and $c$ is an auxiliary mode that is traced out (i.e., the anticlone mode). This Hamiltonian has the singlet form and is thus invariant over the Poincaré sphere (of course we can freely rotate the anticlones because they are traced out). Hence it is valid for any two orthogonal polarizations and we can write $a$ and $a^\perp$ instead of the arbitrary horizontal and vertical polarizations $a_h$ and $a_v$. The resulting propagator $U_t = \exp[\eta g(a^\dagger c^\dagger − a^\dagger c^\dagger)]\exp[−g(a^\dagger c^\dagger − a^\dagger c^\dagger)] = UU_1$ decomposes into a product of orthogonal polarization terms. In Appendix A we show how the “disentanglement theorem” (A6) can be used to express $U$ in the following ordered form:

$$U = e^{T a^\dagger c^\dagger C_g^{−(a^\dagger c^\dagger + c^\dagger a^\dagger + 1)}}e^{−T_\eta ac^\dagger},$$

where $T_\eta = \tanh(g)$ and $C_g = \cosh(g)$. The reason why such reordering formulas exist is that the set of operators $[a^\dagger b^\dagger,a^\dagger b^\dagger,a^\dagger a^\dagger a^\dagger a^\dagger b^\dagger b^\dagger]$ is closed with respect to the commutator, see Appendix for details. Initially the mode $c_{\perp}$ is taken to be in the vacuum state $|0⟩$ (i.e., an empty idler mode in a down-conversion experiment, or a totally inverted atomic
population in an EDFA). The propagator acting on the vacuum state \( |c_⊥ \rangle \) is
\[
C_A = U |0 \rangle_{c_⊥} = e^{T_A^{\dagger} c_⊥^{\dagger}} C_g^{\text{a}\dagger} |0 \rangle_{c_⊥}.
\] (3)

A similar expression for \( C_A^c \) can be obtained for the orthogonal mode \( a_⊥ \). If we put the two modes together the universal amplification is then given in the usual terms of the generalized evolution by the superoperator \( S_A(\rho) \) acting on the input state \( \rho \)
\[
S_A(\rho) = \text{tr}_{c_⊥} C_A^c C_A^c \rho C_A^c C_A^c, \tag{4}
\]
where
\[
\text{tr}_{c_⊥} C_A^c C_A^c = \sum_i C_i^c \rho C_i^c
\text{ and } C_A^c = \frac{\text{tanb}(\theta_i a_i^{\dagger}) \cos(g)}{\sqrt{\theta_i a_i^{\dagger}}}.
\]
To find the fidelity of this cloning process we need to find the evolution of the photon number operator \( a_1^{\dagger} a_1 \) → \( U_1^{\dagger} a_1^{\dagger} a_1 U_1 \).

In Appendix B we show that, in general, it is possible to obtain the mean values of any power of the photon number operator, together with any higher-order correlation function, from the knowledge of the mean value of the characteristic function \( N(k) = \text{tr} e^{k a_1^{\dagger} a_1} \rho \). The reordering relations of Appendix A can be used to show that the operator \( e^{k a_1^{\dagger} a_1} \) is transformed by the universal cloner to
\[
C_A^{\dagger} e^{k a_1^{\dagger} a_1} C_A = e^{k a_1^{\dagger} a_1} (C_g^{\dagger} S_g^{\dagger} e^\chi)^{k a_1^{\dagger} a_1}.
\] (5)

The result (B5) implies that from a single-photon input state \( |1 \rangle \) a universal cloner will yield a number of photons \( n_1 = \sum_i |C_i^c| e^{k a_1^{\dagger} a_1} C_A^c |1 \rangle |_{k=0} \) in the same polarization mode as this input, while the orthogonal polarization mode will be populated by spontaneous emission \( n_0 = \sum_i |C_i^c| e^{k a_1^{\dagger} a_1} C_A^c |0 \rangle |_{k=0} \), corresponding to the amplification of the vacuum state. Using Eq. (5) we obtain the well-known result \( n_1 = 2 \sinh^2(g) + 1 \) and \( n_0 = \sinh^2(g) \). The fidelity of the cloning process is defined as the ratio of the photon number in the input mode to the total photon number after the amplification. The optimal fidelity for large gains is then 2/3. In Appendix D we show that the above treatment is also valid for universal cloners based on doped fiber amplification.

### B. Phase covariant cloning machine

Phase covariant amplification is the cloning procedure that produces equally good and optimal clones of all states lying on a great circle of the Poincaré sphere (e.g., the equator). For photonic polarization qubits it can be achieved \([13,14]\) in degenerate collinear parametric type II down-conversion. Contrary to the case of universal cloning described earlier, here all the photons produced are kept in the output state. Hence in the ideal lossless case the transformation is unitary.

The Hamiltonian of the process reads
\[
H = i \chi a_1^{\dagger} a_1 + \text{H.c.},
\] (6)
with \( \chi \) proportional to the nonlinear \( \chi^{(2)} \) susceptibility and to the power of the pump, which is considered to be classical. Any choice of basis \( \{a_\phi, a_\phi^{\dagger}\} \) with \( a_\phi = \sum_i a_i^{\dagger} (a_\phi + i a_\phi^{\dagger}) \) defines the same great circle of the Poincaré sphere that we henceforth call the equator. One can rewrite the Hamiltonian in a form explicitly invariant on this equator
\[
H = i \chi \left( a_\phi^{\dagger} a_\phi + a_\phi^{\dagger} a_\phi \right) + \text{H.c.}
\] (7)

Henceforth, we omit the index of the particular basis, writing \( a \) and \( a^{\dagger} \) for \( a_\phi \) and \( a_\phi^{\dagger} \), respectively. The evolution propagator \( U_t = \exp(-itH) \) decouples on the two orthogonal polarization modes \( U_t = U_t \otimes U_t \) where
\[
U_t = e^{i(\alpha_2 - \alpha_1)} = e^{i(T_0 a_1^{\dagger} - T_0 a_1)} e^{-i(T_1 a_1^{\dagger} - T_1 a_1)},
\] (8)
with \( C_g = \cosh(g) \), \( T_g = \tanh(g) \), and \( g = t \chi \). To derive the second equality we again used the disentanglement theorem (A6). The propagator for the orthogonal mode \( a_1 \) has the same form. In an analogous way to the previous treatment of the universal cloner, the reordering techniques of Appendix A can be used to show that the operator \( e^{k a_1^{\dagger} a_1} \) is transformed by the amplification process to \( U_1^{\dagger} e^{k a_1^{\dagger} a_1} U_1 \)
\[
U_1^{\dagger} e^{k a_1^{\dagger} a_1} U_1 = e^{-\frac{i}{2} e^{-\frac{i}{2} (\frac{T_0}{C_g^{\dagger} S_g^{\dagger} e^\chi})^2}} \left( e^{-k C_g^{\dagger} S_g^{\dagger} e^\chi} - (a^{\dagger} a + 1) \right)
\times e^{-\frac{i}{2} (\frac{T_0}{C_g^{\dagger} S_g^{\dagger} e^\chi} - 1)^2}.
\] (9)

From this expression we obtain photon numbers of \( n_1 = 3 \sinh^2[g] + 1 \) and \( n_0 = \sinh^2[g] \) for input states \( |1 \rangle \) and \( |0 \rangle \), respectively. The fidelity of cloning a qubit on the equator is then \( F = 3/4 \) in the limit of large gains.

We emphasize that the phase covariant cloning is indeed bad in the \( h-v \) basis: From the form of the Hamiltonian \( (6) \) it is clear that the cloner puts the same number of photons in \( h \) and \( v \) modes and the initial difference in their populations is conserved. So the states \( U_t |1_h \rangle \) and \( U_t |1_v \rangle \) are different by only one photon in each mode and, of course, when the total population becomes large, such a difference is unobservable with any realistic measurement precision.

### C. Measure-and-prepare cloning machine

The operation of both the universal and phase covariant cloning machines relies on quantum processes. It is interesting to see how these cloners compare to a more “classical” approach: One can simply measure the input state, in an arbitrary basis and produce a stronger output according to the measurement result. An illustration of how such a device could be implemented is shown in Fig. 2.

![FIG. 2. (Color online) A possible implementation of a measure-and-prepare cloning machine: the two wave plates have the same angle.](Image)
The symmetry of this cloning machine is determined by the set of measurement bases among which a random basis is chosen before each measurement. For example, in the setup of Fig. 2, the use of half-wave plates would allow for a random choice of basis in a great circle of the Poincaré sphere. Restricting our discussion to the case of single-photon polarization qubits and large gains allows one to draw an analogy between this cloner and a phase covariant cloner, as we show in the following [9]. The single photon is measured in a basis \{\alpha_\phi, \alpha_{\phi \perp}\}, with randomly chosen \phi. Depending on the measurement result, this cloner will prepare an output coherent state in one of the two polarizations: \{\alpha_\phi\} or \{\alpha_{\phi \perp}\}. Accordingly, for any input state \rho_0, the output state reads

\[
\rho = 2 \int_0^{2\pi} \frac{d\phi}{2\pi} \langle 1_\phi | \rho_0 | 1_\phi \rangle |\alpha_\phi\rangle \langle \alpha_\phi |,
\]

where the factor of 2 is due to the fact that for each measurement basis there are two possible outcomes that give twice the same term after the integration.

To prove the optimality of this cloning procedure, consider an input state |1\rangle = a^\dagger |0\rangle on the equator

\[
\rho = \int \frac{dp}{\pi} \frac{c_\phi s_\phi}{|c_\phi|^2} |s_\phi \alpha_{a \perp}\rangle \langle s_\phi \alpha_{a \perp}|,
\]

where \(c_\phi, s_\phi\) represent \cos(\phi) and \sin(\phi), respectively. The output photon numbers are then given by

\[
n_a = 2|a|^2 \int \frac{dp}{\pi} c_\phi^2 = \frac{3}{4} |a|^2,
\]

\[
n_{a \perp} = 2|a|^2 \int \frac{dp}{\pi} c_\phi^2 s_\phi^2 = \frac{1}{4} |a|^2.
\]

It is interesting to note that the fidelity of this process is 3/4, the same as for the optimal phase covariant cloner, in the limit of large gains. Nevertheless, the output states of the two different machines are very different: while the phase covariant cloner performs a unitary transformation, and therefore preserves entanglement, the measure-and-prepare cloner trivially breaks the entanglement by projecting the state on a specific basis before amplification.

Just as the phase covariant cloner, the measure-and-prepare cloner presented previously is bad for the h-\nu basis. Actually it is even worse. The input states |1_\nu\rangle and |1_\nu\rangle\perp are both sent to the same output \rho_{hv} = \int \frac{dp}{2\pi} |\alpha_\phi\rangle \langle \alpha_\phi|.

A measure-and-prepare cloner with the same symmetry and fidelity as the universal cloner can be defined in a similar way, by choosing the measurement basis amongst the full set of points on the Poincaré sphere. The fact that we choose coherent states as the output of the measure-and-prepare cloner is only suggested by the simplicity of a potential realization, nothing prevents one from designing such a cloner preparing states with any other photon number distribution. For example, with thermal states it gives a photon number distribution more similar to that of the state produced by the universal and phase covariant cloners.

### IV. DETECTION OF A CLONED STATE

To evaluate what can be inferred from the detection of an amplified state, it is important to have a model of the available detector. In our case, we want to know how this state would be detected by the human eye: a lossy threshold detector, which is a combination of a loss mechanism and a von Neumann projector on a part of Hilbert space. We describe the transmission loss by a beam splitter coupling an optical mode \(a \rightarrow a \sqrt{\eta} + \sqrt{1-\eta}\) to an inaccessible environment mode \(e\) that is initially empty (\(\hbar \omega \gg kT\) for visible wavelength at room temperature). We can express the loss channel \(C_\eta\) as follows:

\[
C_\eta = e^{\gamma(e^\nu - a^\dagger e)} |0\rangle_e = e^{e^{\tan(\gamma) a} \nu} |0\rangle_e,
\]

with \(\gamma = \cos^2(\nu)\), where we used (A6) for the second equality. An initial one-mode state \(\rho_0\) after a lossy transmission becomes \(\rho_\eta = \text{tr}_C \eta \rho_0 C_\eta = \sum_{n \geq 0} C_\eta C_n^\dagger \rho C_n^\dagger\) with \(C_\eta = \frac{1}{\sqrt{\eta}} \cos(\nu) a e^{\gamma(e^\nu - a^\dagger e)}\). Of course, a polarization-encoded qubit undergoes transmission loss in both of the basis modes \(a\) and \(a\perp\). If isotropic, such a loss channel is given by the product \(C_\eta C_n^\dagger\) with the same transmission \(\eta\). Its action on an input state \(\rho\) is given by the superoperator

\[
S_L(\rho) = \text{tr}_{e,e'} C_\eta C_{\eta \dagger}^\rho C_n^\dagger C_n.
\]

One can verify that this expression is indeed basis independent. The isotropic loss \(S_L\) and the universal amplification \(S_A\) are the two simplest processes with universal symmetry.

### B. Threshold detectors

Let us consider the usual nonphoton-number resolving detector with efficiency \(\eta\). The probability of detection of the Fock state \(|n\rangle\) is given by

\[
\langle n | \hat{P}_\eta | n \rangle = 1 - (1 - \eta)^n.
\]

Such an operator \(\hat{P}_\eta\) (the subscript \(s\) represents “see”) is given by \(C_\eta^\dagger \hat{P}_\eta C_\eta\), with \(\hat{P}_\eta = 1 - |0\rangle |0\rangle\langle 0|\langle 0|\) an ideal detector-von-Neuman projector and \(C_\eta\) is the loss channel described previously (it is possible to add a small universal cloner \(C_A \hat{P}_\eta C_A\) to model the dark counts in the detector). It is natural to introduce a more general family: the threshold detectors, analogous to the ideal single-photon detector. An ideal threshold detector always “sees” the Fock states with the photon number \(n\), if \(n\) is bigger then the threshold \(\theta\), and never “sees” Fock states with smaller photon number. In a realistic situation such an ideal detector is preceded by loss, giving the operator

\[
\hat{P}_\eta = C_\eta^\dagger \left( \mathbb{1} - \sum_{n > \theta} |n\rangle \langle n| \right) C_\eta = 1 - \hat{P}_{\theta \eta}.
\]

In Appendix B we show that for any state \(\rho\) a projection on any Fock state can be recovered from the scalar function \(\Pi(z)\), which we introduce loss and use the rearrangement formulas of Appendix A, becomes

\[
\Pi(z) = \text{tr} \rho C_\eta^\dagger e^{a^\dagger a} C_\eta = \text{tr} \rho (\eta z + 1 - \eta) a^\dagger a.
\]
To make the formulas shorter we introduce the scalar function \(\pi q(z) = (\eta z + 1 - \eta)\). A situation where a detector with an efficiency \(\eta\) is preceded with a transmission channel with \(t = \eta T\) is equivalent to a detector with an effective efficiency of \(\eta = \eta_T tr\).

**C. Detecting with the human eye**

The human eye is a surprisingly efficient detector with virtually no dark counts. At low light intensities rod cells are responsible for photon detection. These cells are densely packed on the retina (\(\sim 10^3\) mm²), where threshold logic is also present to provide noise reduction [18]. The human eye can then be modeled as a lossy threshold detector (16) with “efficiency” \(\eta \approx 7\%\) and a threshold \(\theta \approx 7\) [19]. The amplified singlet pair contains enough photons to imagine Bell-type experiments with the naked human eye. In the following section we will describe in more detail how the eye can be combined with simple logic to produce a “macro-qubit” analyzer.

**D. “Macro-qubit” analyzer**

Now we describe the full detection scheme on the amplified side (Fig. 3). First the photons pass through a variable linear optical element that stands for the choice of the measurement basis among some variants (i.e., the setting of the measurement), then the two orthogonal polarization modes (\(a\) and \(a_\perp\)) are separated on a polarizing beam splitter (PBS) and sent to a corresponding threshold detector. We distinguish three possible outcomes. First, there are the two conclusive events (“\(P_a\)” and “\(P_{a\perp}\)”) when only one of the two detectors sees. In these cases it is intuitively clear that, statistically, in the mode that triggered the threshold there were more photons than in the one that did not. Second, there is the inconclusive event “\(P_{null}\)” that occurs when both detectors see or both do not. These three outcomes form a POMV because they describe all the possible events. More formally, we can write the corresponding operators as

\[
\hat{P}_a = P_n^0(a)\hat{P}_{ns}(a_\perp), \\
\hat{P}_{a\perp} = P_n^0(a)\hat{P}_{ns}(a), \\
\hat{P}_{null} = 1 - \hat{P}_a - \hat{P}_{a\perp}. 
\]

According to the results shown in Appendix B, from the knowledge of the mean value \(\langle \pi q(z)\rangle^a\pi q(z)^{a, a_\perp} = f(z, z_\perp)\) on a given quantum state we can directly infer the mean values of \(\hat{P}_a, \hat{P}_{a\perp}\), and \(\hat{P}_{null}\) on the same state

\[
\langle \hat{P}_a \rangle = \frac{\partial f(z, z_\perp)}{\partial z} \left| \frac{1 - z_\perp}{1 - z} \right|_0, \\
\langle \hat{P}_{a\perp} \rangle = \frac{\partial f(z, z_\perp)}{\partial z} \left| \frac{1 - z_\perp}{1 - z} \right|_0, \\
\langle \hat{P}_{null} \rangle = 1 - \langle \hat{P}_a \rangle - \langle \hat{P}_{a\perp} \rangle. \quad (19)
\]

**V. INFERRING MICRO-MICRO ENTANGLEMENT**

In this section we consider the cloning machine as part of Bob’s measurement apparatus and ask ourselves what can be concluded from the seen quantum correlation. More specifically, the question is whether one can conclude anything about the micro-micro quantum state produced by the source (see Fig. 1). Recall that Alice’s measurement apparatus is conventional, while Bob’s apparatus first uses one of the amplifiers presented in Sec. III and then the “macro-qubit” analyzer presented previously (Fig. 3) to measure the amplified state. The two measurement apparatuses look very different. However, on an abstract level they are similar. Both measure the polarization state of single-photons, both accept a polarization basis as measurement setting, and both either produce a definite result or, with some probability, produce no result at all. The similarity goes on further. The probability that a measurement fails to produce an outcome is independent of the measurement setting, as proven in the following. Consequently, if both Alice and Bob’s apparatuses are inserted in black boxes then, from the outside, one cannot distinguish them. The question of micro-micro entanglement between the two photons produced by the source is thus not different in our case as it is in the usual, more common, measurement configuration, in particular, in the configuration where Bob uses a measurement apparatus similar to Alice’s (with an efficiency that matches that of his “measurement apparatus with human eyes”).

Accordingly, all the usual machinery of entanglement witnesses also apply to our configuration. In particular, one can see entanglement, that is, one can conclude that the two-photon source produces entanglement from the correlation observed with the naked eye, as one could conclude using a standard PBS followed by single-photon detectors. In both cases one admits that the detectors have a finite efficiency, independent of the measurement settings, and that the input state is well described as a pair of qubits (i.e., as a quantum state in the \(2 \otimes 2\) Hilbert space).

We conclude this section by emphasizing that the analysis would be completely different if we did not assume the cloning machine to be part of the measurement apparatus. In that case one would be looking at possible entanglement between Alice’s single-photon and Bob’s large multiphoton quantum state, as discussed in the next section. The analysis would also be deeply different if one were looking for nonlocal correlations instead of mere entanglement. Indeed, as already mentioned in the Introduction, entanglement is a quantum concept and can thus be analyzed within the usual Hilbert space machinery, accepting that measurement apparatuses sometimes fail to produce results (e.g., because of inefficient detectors), while the concept of nonlocal correlations goes
beyond quantum physics. Hence, for the latter, no-result events cannot be neglected, as briefly analyzed in the end of the Sec. V.F.

A. Cloning as part of the detection apparatus

Instead of considering the evolution of the input state through cloning we can see the cloning as a part of the detection process (i.e., as acting on the measurement apparatus). Of course, from this perspective we completely disregard micro-macro entanglement, however, it is much better fitted for analyzing the micro-micro entanglement aspect. All the micro-macro entanglement, however, it is much better fitted through cloning we can see the cloning as a part of the detection process (i.e., as acting on the measurement apparatus)...

\[ \tilde{\Pi}(\eta, z, z', \ldots) = \sum_i W_i \pi_\eta(z)^{a_i} \pi_\eta(z')^{a_i} W_i^\dagger. \] (22)

The three points are here because the evolution can depend on various parameters such as gain and internal losses. We then explicitly restrict the operator \[ \tilde{\Pi} \] on the input Hilbert space by finding the nine scalar functions \[ \tilde{\Pi}_{ij} = \langle i | \tilde{\Pi} | j \rangle \] belonging to the set of basis vectors of the input Hilbert space \{±, −, 0\}. Finally, by applying one of the relations from Eq. (19) to these functions \[ \tilde{\Pi}_{ij} \], we find the nine numbers that represent the corresponding operators of \{\[\hat{\rho}_a, \hat{\rho}_b, \hat{\rho}_{null}\]}. The contribution to the correlation visibility that we obtain from a measurement in the setting \{\[a, a', b, b'\] and \{\[b, b'\] is by definition \(\langle \langle \hat{\rho}_a - \hat{\rho}_{null} \rangle | (|1_b\rangle\langle1_b| - |1_{b'}\rangle\langle1_{b'}|) \rangle \). After postselection the observed visibility becomes

\[ V_{\{a, a'\}} = \frac{\langle \langle \hat{\rho}_a - \hat{\rho}_{null} \rangle | (|1_b\rangle\langle1_b| - |1_{b'}\rangle\langle1_{b'}|) \rangle}{\langle \langle \hat{\rho}_a + \hat{\rho}_{null} \rangle \rangle}. \] (23)

For the singlet state this mean value is

\[ V_{\{a, a'\}} = \frac{(\hat{\rho}_{a}++) + (\hat{\rho}_{a}--) - (\hat{\rho}_{a}++) - (\hat{\rho}_{a}--) + (\hat{\rho}_{a}++) + (\hat{\rho}_{a}--)}{3}. \] (24)

Above we have shown how the correlation visibility for a particular amplification protocol can be evaluated. Next we will derive a bound on this correlation visibility that implies the presence of entanglement in the initial micro-micro state. To do this, in the following section we will introduce an entanglement witness.

B. Entanglement witness

The only entanglement witness that we will use in this paper is the one introduced in [20]. It has the following form:

\[ W = |\langle \tilde{J}_A \tilde{J}_B \rangle| - |N_A N_B|, \] (25)

where \[ \tilde{J}_A \] and \[ \tilde{J}_B \] denote Stokes vectors (total polarization) on parts A and B, while \[ N_A \] and \[ N_B \] are the total number of photons for A and B. For any separable state \[ \sum_{i} \rho_i \sigma_i \otimes \sigma_i \] we can bound \[ |\langle \tilde{J}_A \tilde{J}_B \rangle| \]

\[ |\langle \tilde{J}_A \tilde{J}_B \rangle| \leq \sum_{i} p_i |\langle \tilde{J}_A \rangle_{\rho_i} \langle \tilde{J}_B \rangle_{\sigma_i}| \]

\[ = \sum_{i} p_i |\langle J_A \rangle_{\rho_i} \langle J_B \rangle_{\sigma_i}| \leq |N_A N_B|, \]

where the sign on the states \[ \rho_i \] and \[ \sigma_i \] means that we choose the basis where only the \[ z \] component of \[ \langle \tilde{J}_\phi \rangle \] is nonzero. Hence, for all separable states one has \[ W \leq 0 \] and the positivity of \[ W \] witnesses the presence of entanglement.

C. On entanglement in \( C^2 \otimes C^2 \)

In the beginning of this section we showed how the expectation value of the correlation visibility can be obtained for each type of amplification. Here our perspective will be completely different: We are given a correlation visibility (that is experimentally measured) and have to decide whether it proves or does not prove the presence of entanglement.

---

3Making the unitary evolution act on the operators \( U^\dagger \hat{O} U \), instead of states \( U \rho U^\dagger \), is called the Heisenberg picture as opposed to the Schrödinger picture. However, when dealing with the generalized evolution \( \sum_i W_i \rho W_i^\dagger \), one should take care when going to the Heisenberg picture because, if we naively write \( \sum_i W_i^\dagger \hat{O} W_i \), we implicitly trace out the auxiliary modes and as a consequence such a transformation is not canonical, in general. To do the thing properly one has to introduce the Langevin noise operators in the operator transformation rules. However, if we are not doing any algebra with the transformed operators, like in the case when the only quantity of interest is \( \langle \hat{O} \rangle \) or \( \langle \hat{O} \rangle \), it is unnecessary and we can stick with \( \sum_i W_i^\dagger \hat{O} W_i \).
in the input state. Within this perspective the presence of entanglement is ensured by the value of the correlation visibility only if this value is impossible to obtain for a separable input state with any detection scheme. Let us first introduce the general detection, as usual its representation in a basis \(\{a, a\perp\}\) is given by the following POVM:

\[
P_+ = \eta |1\rangle\langle 1| + \frac{1}{\eta} \mathbb{I}, \quad P_- = \eta |1\perp\rangle\langle 1\perp| + \frac{1}{\eta} \mathbb{I},
\]

\[
P_{\text{null}} = (1 - \eta - \xi) \mathbb{I} \quad \text{with} \quad \eta + \xi < 1,
\]

which describes a detector with the efficiency \(\eta\) and noise rate \(\xi\). The total probability of a conclusive result is then a multiple of identity \(P_+ + P_- = (\eta + \xi) \mathbb{I}\) and \(P_+ - P_- = \eta (|1\rangle\langle 1| - |1\perp\rangle\langle 1\perp|)\). The correlation visibility contribution after the postselection (23) is given by

\[
\eta \frac{1}{\eta + \xi} ((|1\rangle\langle 1| - |1\perp\rangle\langle 1\perp|)_{a\ast} (|1\rangle\langle 1| - |1\perp\rangle\langle 1\perp|)_{b\ast}).
\]

The total visibility \(V = V_{a,a\ast} + V_{a'\perp,a'\ast} + V_{a',a\ast}\), which is the sum of the contributions of the three orthogonal bases on the Poincaré sphere, is equal to

\[
|V| = \frac{\eta}{\eta + \xi} |\langle \sigma_a | \sigma_b \rangle|,
\]

where \(\sigma\) is a vector of Pauli matrices \((\sigma_x, \sigma_y, \sigma_z)\). The value of \(|V|\) is maximal for \(\xi = 0\). Using the entanglement witness (25), which for two entangled photons \(a\) and \(b\) reads \(W = |\langle \sigma_a | \sigma_b \rangle| - 1\), we find that for a separable state

\[
|V_{a,a\ast}| \leq 1/3.
\]

For cloning machines with equatorial symmetry, there are two settings on the equator that give an equally good contribution to the visibility \(V_{a,a\ast}\) (24) and the \(h-v\) contribution that is identically zero for the measure-and-prepare cloner and negligible for the phase covariant cloner (see discussion at the end of the corresponding sections). So for these two cloning machines the bound (29) reads

\[
|V_{a,a\ast}| \leq 1/2.
\]

### D. Universal cloner

The evolution for the universal amplification is known to decouple for the two orthogonal polarizations modes. For one of the polarization modes \(C_g \pi_{\eta}(z) a^{\dagger} a C_g^\dagger\) is \(\pi_{\eta}(z) a^{\dagger} a (C_g^2 - S_g^2 \pi_{\eta}(z))\), and the function \(\hat{\Pi}(\eta, g)\) is a product of two such terms for both polarization modes. The restriction to the input Hilbert space gives

\[
\hat{\Pi}(\eta, g)_{++} = \pi_{\eta}(z) \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-1} \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-1},
\]

\[
\hat{\Pi}(\eta, g)_{--} = \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-1} \pi_{\eta}(z \perp) \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-2},
\]

\[
\hat{\Pi}(\eta, g)_{00} = C_g^2 - S_g^2 \pi_{\eta}(z),
\]

(32)

All the nondiagonal terms are 0. The different functions \(\hat{\Pi}_{ij}\), together with one of the three relations (19), allow the direct calculation of the corresponding detection probability, which can be used to find the visibility (24).

### E. Phase covariant cloner

The situation is similar for the phase covariant cloner. The evolution is decoupled for the two polarization modes, the generating function is transformed to \(U^\dagger \pi_{\eta}(z) a^{\dagger} a U\), that is, the complicated expression (9), where we replace \(e^{i\theta} \rightarrow \pi_{\eta}(z)\). But when we make the restriction, we obtain a simpler form that is similar to Eq. (32)

\[
\hat{\Pi}(\eta, g)_{++} = \frac{\pi_{\eta}(z)}{\left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]} \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-2},
\]

\[
\hat{\Pi}(\eta, g)_{--} = \frac{\pi_{\eta}(z \perp)}{\left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]} \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-2},
\]

\[
\hat{\Pi}(\eta, g)_{00} = \left[ C_g^2 - S_g^2 \pi_{\eta}(z) \right]^{-2},
\]

(33)

### F. Measure-and-prepare

The evolution of the input state \(\rho_0\) through the measure-and-prepare amplifier is given in Eq. (10), making it act on \(\pi_{\eta}(z) a^{\dagger} a \pi_{\eta}(z) a^{\dagger} a\) gives

\[
\int d\phi \frac{1}{\pi} \left|1\phi \right| \left( \alpha c \phi | \alpha c \phi \right) \left| \alpha s \phi | \alpha s \phi \right\rangle \left\langle \alpha s \phi \right| \alpha s \phi \rangle,
\]

that is,

\[
\hat{\Pi}(\eta \alpha) = \int d\phi \frac{1}{\pi} e^{-\eta |\alpha|^2 |z| z\perp} \left|1\phi \right| \left|1\phi \right\rangle.
\]

To make the restriction to the initial Hilbert space we simply rewrite \(\left|1\phi \right| \left|1\phi \right\rangle\) in the basis \([|1\rangle, |1\perp\rangle]\)

\[
\hat{\Pi}(\eta \alpha)_{\text{Mr}} = \int d\phi \frac{1}{\pi} \left( \begin{array}{cc} c_\phi & c_{\phi} s_{\phi} \ 0 & s_{\phi} \end{array} \right) e^{-\eta |\alpha|^2 |z| z\perp}.
\]

(35)

The integration kills the off-diagonal elements while the diagonal can be expressed with the modified Bessel function \(I_0(z) = \int \frac{e^{-i\pi}z}{\pi} \) as

\[
\hat{\Pi}(\eta \alpha)_{++} = 2 e^{-\eta |\alpha|^2 |z| z\perp} \frac{1}{|\alpha|^2} \partial_z \left[ e^{|\alpha|^2 i z z\perp} I_0 \left( \frac{|\alpha|^2 z^2 - z\perp}{2} \right) \right],
\]

\[
\hat{\Pi}(\eta \alpha)_{--} = 2 e^{-\eta |\alpha|^2 |z| z\perp} \frac{1}{|\alpha|^2} \partial_z \left[ e^{|\alpha|^2 i z z\perp} I_0 \left( \frac{|\alpha|^2 z^2 - z\perp}{2} \right) \right].
\]

(36)
G. What does the correlation visibility tell us?

In Figs. 4 through 6 we plotted the observed correlation visibility $V_{a,a_i}$, the probability of a conclusive event $P$ (which tells us the amount of postselection), and the bound above which the visibility proves the entanglement of the initial photon pair. We see that with each of the three different amplification types we achieve visibilities that are higher than this bound, consequently one can “see” micro-micro entanglement with any of the cloning machines described. Surprisingly, the highest observed visibility is that seen with the measure-and-prepare cloner, and we know that its output is not entangled with Bob’s photon (the entanglement is broken by the projective measurement done by the cloner). This illustrates the fact that the measurement of correlation visibility does not prove the micro-macro entanglement, indeed the separable state prepared by the measure-and-prepare cloner shows that such a naive analysis does not apply.

We can also analyze the observed correlation visibility from the perspective of Bell inequalities. The famous CHSH inequality introduced in [21] gives a bound on the observed visibility

$$|V_{a,a_i}^{\text{CHSH}}| > \frac{1}{\sqrt{2}} \approx 0.7,$$

below which the correlations can not be reproduced by any local model. As shown in Fig. 6, the correlation visibility observed for the measure-and-prepare cloner can be higher then the CHSH bound. A priori this seems to be a paradox, however, it is well known that the postselection opens the detection loophole, in particular, in the analysis of Clauser et al. [21] no measurement result can be disregarded. Again the importance of the detection loophole is fully revealed by this example, indeed if one is not careful, one may easily wrongly conclude that a Bell inequality is violated even when the quantum state under consideration is separable, and this is true even if the probability of a successful result is independent of the measurement basis. Remark that without postselection the observed correlation visibility is given by $P V_{a,a_i}$, which never exceeds the CHSH bound $1/\sqrt{2}$ for all of the presented cloning machines.

To finish, we note that these results can be generalized for other types of threshold detectors, such as the orthogonality filter introduced in [14].

VI. MICRO-MACRO ENTANGLEMENT

In this section we ask ourselves whether the different cloning machines presented in Sec. III preserve entanglement, that is, whether after amplification of Alice’s photon, Bob’s single-photon is entangled with Alice’s many photons. Here we consider this as a question of principle, hence we do not consider which measurement could reveal the entanglement.

To apply the criteria (25) to the present case we choose a basis for the vectors, let it be the poles of the Bloch sphere $h-v$ component denoted “z” and two components on the equator denoted “x” and “y”. Each of the components $J_i^A J_i^B = J_i \sigma_i$ in this basis has the form $(a_i^1 a_i^+ - a_i^+ a_i^1)(b_i^1 b_i^+ - b_i^+ b_i^1)$. For this purpose we place ourselves in the Heisenberg representation and apply the evolution on these operators while the state remains $|\psi^+\rangle$. The $b$ photon operators are not affected by the evolution, all that can happen is that we lose Bob’s photon, but as we use it to trigger the experiment these cases
are excluded (for the same reason $N_B = 1$). Thus we know the value of $b' | b$ at all times and can make the average on Bob’s side so that

$$\langle \psi^- | J_x^\dagger \sigma_z^\dagger | \psi^- \rangle = \langle 1_1 | (a_1^\dagger a_1 x - (a_{1\perp}^\dagger a_{1\perp})_x) | 1_1 \rangle,$$

where $| 1_1 \rangle = a^\dagger_1 | 0 \rangle$. Remark that a transmission loss after the amplification has a simple effect $W \rightarrow W$ with $\eta$ the transmission efficiency.

### A. Phase covariant cloner

In the ideal case the phase covariant amplification leads to a unitary evolution, in which case the initial entanglement is trivially preserved. However, if there are some losses anywhere the unitarity is broken. Here we treat the case where losses occur during cloning. For the phase covariant amplification we know that $J_x J_x = J_y J_y$ and because the evolution of $a$ and $a_\perp$ decouples ($J_x J_y = 1_1$). For the arbitrary mode $\langle \psi_1 | (a_1^\dagger a_1) | 1_1 \rangle = \langle 0 | (a_1^\dagger a_1) | 0 \rangle$ while the total photon number expressed in an equatorial basis is $N = 1_1 | (a_1^\dagger a_1) | 1_1 \rangle + | (a_{1\perp}^\dagger a_{1\perp})_x | 0 \rangle$ implying that

$$W = \langle 1_1 | (a_1^\dagger a_1) | 1_1 \rangle - 3 \langle 0 | (a_1^\dagger a_1) | 0 \rangle + \langle J_x J_y \rangle.$$

The operator $| (a_1^\dagger a_1) = \lambda | (a_1^\dagger a_1) | 0 \rangle - f,$

where the damping is a result of a weak interaction with a collection of empty environmental modes (such as absorption and geometrical scattering), $f$ is the Langevin-noise fluctuation induced by the statistics of these modes. We take $< f > = 0$ which corresponds to the environment in the vacuum state before the interaction. In the equatorial modes the evolution is diagonal for the quadrature operators $x = \frac{1}{\sqrt{2}}(a_1^\dagger + a_1)$ and $p = \frac{i}{\sqrt{2}}(a_1^\dagger - a_1)$. With $(a_1^\dagger a_1)_x = \frac{1}{2}(x^2 + p_1^2 - 1)$ and $H = \frac{1}{2}(x^2 + p_1^2)$ the equations of motion for the squares of the quadratures are

$$\frac{d}{dt} | x_1^2 \rangle = (2\chi - \lambda) | x_1^2 \rangle + \frac{1}{2} \lambda,$$

$$\frac{d}{dt} | p_1^2 \rangle = (-2\chi - \lambda) | p_1^2 \rangle + \frac{1}{2} \lambda,$$

which is straightforward to solve, but yields a long expression. In the polar modes “$z$” the commutator $[H, a_{1\perp}^\dagger a_{1\perp} - a_{1\perp}^\dagger a_{1\perp}] = 0$ and the only thing that acts on this operator is damping, thus $\langle J_x J_y \rangle = e^{-2\lambda t}$. After rescaling $(\lambda t, \chi t) \rightarrow (\lambda, \chi)$ we obtain

$$W = 1 + e^{-\lambda} - \frac{2\lambda}{(2\chi)^2 - \lambda^2} \{ e^{-\lambda}(2\chi S_{2\chi} + \lambda C_{2\chi} - \lambda) \},$$

with $S_{2\chi} = \sinh 2\chi$ and $C_{2\chi} = \cosh 2\chi$. While the number of photons is

$$N = 2e^{-\lambda} C_{2\chi} + \frac{2\lambda [e^{-\lambda}(2\chi S_{2\chi} + \lambda C_{2\chi} - \lambda)]}{(2\chi)^2 - \lambda^2}.$$

In Fig. 7 we plot the parametric curves for $W = 1$ and $W = 0$ as functions of the total photon number and the amplification or damping ratio that describes the quality of the amplification.

### B. Universal cloner

For the universal cloner all the three components of $(\hat{J} \hat{a})$ are the same, and with the photon number being $N = (1 | a_1^\dagger a_1 | 1) + (0 | a_1^\dagger a_1 | 0) = 1$ the violation becomes $W = 2 (1 | a_1^\dagger a_1 | 1) - 4 (0 | a_1^\dagger a_1 | 0)$ for an arbitrary mode, let it be the mode $a_n$. The damped Heisenberg equation (40) for the Hamiltonian (1) gives the complete set of differential equations

$$\frac{d}{dt} | a_n^\dagger a_n \rangle = \chi | (a_n^\dagger c_n^\dagger + a_n c_n) - \lambda | a_n^\dagger a_n \rangle,$$

$$\frac{d}{dt} | c_n^\dagger c_n \rangle = \chi | (a_n^\dagger c_n^\dagger + a_n c_n) - \lambda | c_n^\dagger c_n \rangle,$$

$$\frac{d}{dt} | a_n c_n \rangle = \chi | (a_n^\dagger a_n + c_n^\dagger c_n) + 1 - \lambda | a_n c_n \rangle.$$

The above system can be diagonalized and solved by standard linear algebra methods yielding (for $(c_n^\dagger c_n) = 0 = 0$)

$$W = 2G(\chi, \lambda) - 2Q(\chi, \lambda),$$

$$N = G(\chi, \lambda) + 2Q(\chi, \lambda),$$

with $G(\chi, \lambda) = \frac{1}{2} e^{-\lambda} [\cosh(2\chi) + 1]$ and $Q(\chi, \lambda) = \frac{1}{4} \{ e^{2\chi} - 1 \} + \frac{1}{2} e^{2\chi} [e^{-2\chi} - 1]$. In Fig. 8 we plot the curves $W = 1$ and $W = 0$ in the plain defined by the number of photons and the quality of the amplification.
C. Loss before the amplification

The entanglement witness $W$ is very fragile in the case where the singlet state is subject to loss of the photon $a$ in the amplified spatial mode (the presence of the other photon $b$ is ensured by the heralding). The input state in this case is

$$\rho = p |\psi^-\rangle\langle\psi^-| + \frac{1 - p}{2} (b^\dagger 0 |0\rangle b + b_+^\dagger 0 |0\rangle b_+).$$

(45)

The value of $W$ is then the sum of the two contributions for the components $p\rho_e = p |\psi^-\rangle\langle\psi^-|$ and $(1 - p)\rho_s = \frac{1 - p}{2} |b^\dagger 0 |0\rangle b + b_+^\dagger 0 |0\rangle b_+$. The first one gives the violation for the ideal lossless case for both the universal cloner and the phase covariant cloner $p(W)_{\rho_e} = 2p$. The second term, however, becomes negative very fast because $\langle J_i \rangle = 0$ for the amplified vacuum $(1 - p)(W)_{\rho_s} = -2(1 - p)n_0$, where $n_0$ is the number of photons for the amplified vacuum. Consequently $W$ is positive if and only if

$$n_0 \leq \frac{p}{1 - p}.$$  

(46)

To prove the entanglement with this witness we must impose a condition on $p$ which becomes more and more restrictive when the number of photons in the amplified state grows. The general situation is, however, different for the universal and the phase covariant amplifiers. For the universal cloner we can indeed show that $S_1(\rho)$ becomes separable for $n_0 = \frac{p}{1 - p}$. While under the assumption of unitarity, the phase covariant cloner preserves the entanglement for any $p \neq 0$ and $n_0$, this is the simple consequence of the fact that the two states $\rho_e$ and $\rho_s$ live in independent sectors of the Hilbert space and consequently the state $\rho$ is always entangled [for example, one can use the positive partial transpose (PPT) criterion [22], $p\rho_e^{\text{PPT}}$ will always have negative eigenvalues that would also be eigenvalues of $\rho^{\text{PPT}}$] and a unitary evolution will only modify the eigenvectors, but not the eigenvalues; note that this simple image does not work when we add loss after the amplification.

VII. CONCLUSION

In conclusion, if one clones one photon from an entangled pair of photons, then one can see quantum correlations with the naked eye. However, the observed correlation allows one to conclude only about entanglement of the initial two-photon pair: One can see only micro-micro entanglement. Nevertheless, cloning with amplifiers, in contrast to measure-and-prepare cloners, does preserve some entanglement; hence there is some micro-macro entanglement, though the detection of micro-macro entanglement requires more sophisticated detection schemes than the mere naked eye.

In this article we also emphasized the danger of eliminating inconclusive data. In entanglement studies this is an acceptable procedure, as one works within standard Hilbert space quantum physics and can thus trust one’s detectors and theory thereof. For the study of nonlocality, however, eliminating inconclusive results can easily lead to the wrong conclusion. This illustrates on a practical example the importance of the detection loophole.

Several questions are left open. For example, one could consider cloning both photons of the initial pair. Another natural question concerns the micro-macro entanglement: How much entanglement is there? Can one detect it experimentally with realistic detectors? We leave these fascinating questions for future work. Likewise, the experimental realizations of the analyzed situations, using the various cloners, are underway and will be discussed in future work.

ACKNOWLEDGMENTS

We would like to thank our colleagues Hugo Zbinden, Nicolas Brunner, and Cyril Branciard for useful discussion and comments. This work was supported by the Swiss FNRS.

APPENDIX A: SPIN GROUPS

Let us recall the following algebraic relation, which is very useful in the context of continuous groups

$$e^B Ae^{-B} = \sum_{n \geq 0} \frac{1}{n!} [B, A]^{(n)},$$

(A1)

where $[B, A]^{(n)}$ means the nested commutator $[B, \ldots [B, A] \ldots ]$ with $B$ appearing $n$ times. The equality can be easily proven by repeatedly differentiating (expanding in its Taylor series) the expression $e^{B/A}e^{-B/\lambda}$ and putting $\lambda = 1$ at the end. Trivially

$$e^B f(A)e^{-B} = f\left( \sum_{n \geq 0} \frac{1}{n!} [B, A]^{(n)} \right),$$

(A2)

for any analytical function $f$. Now, following [23] we introduce a set of operators $\sigma_+, \sigma_-, \sigma_z$ with spin commutators $\{\sigma_+, \sigma_\pm\} = \pm 2\sigma_\pm$. In the following we will consider Hamiltonians that are time-dependent linear combinations of these operators. Applying Eq. (2) we derive some formulas useful for rearranging propagators

$$e^{k\sigma_z f(\sigma_\pm)} = (e^{k\sigma_z} f(\sigma_\pm)) e^{k\sigma_z},$$

(A3)

$$e^{k\sigma_+ f(\sigma_-)} = f(\sigma_- k\sigma_+ + k^2 \sigma_\pm) e^{k\sigma_+},$$

(A4)

$$e^{k\sigma_- f(\sigma_+)} = f(\sigma_+ k\sigma_- + k^2 \sigma_\pm) e^{k\sigma_-}.$$  

(A5)

Adding some structure we can identify two different sets $\{\sigma_+, \sigma_-, \sigma_z\}_{\mp}$ according to $\sigma_z = \pm \sigma_\pm$. In both cases we construct unitary operators of the form

$$U_+ = e^{i(\sigma_- - \sigma_+)} \quad U_- = e^{i(\sigma_+ - \sigma_-)}.$$  

We rewrite these expressions as

$$U_+ = e^{i\tan \lambda \sigma_z} e^{-i \ln(\cosh \lambda) \sigma_\pm} e^{-i \tan \lambda \sigma_-},$$

$$U_- = e^{i\tanh \lambda \sigma_z} e^{-i \ln(\cosh \lambda) \sigma_\pm} e^{i \tanh \lambda \sigma_-}.$$  

(A6)

This can be shown as follows. Suppose $U_{\pm} = e^{\hbar \sigma_z} e^{\hbar \sigma_\pm} e^{\hbar \sigma_-}$ derives both sides by $\lambda$, then pull all the pre-exponential factors on the left using Eqs. (3) through (5) and multiply by $U^\dagger_{\pm}$ from the right. We obtain

$$\sigma_+ \pm \sigma_- = f' \sigma_+ + g'(\sigma_z - 2 f \sigma_+) + h' e^{-i \lambda} (\sigma_+ + f \sigma_- - f^2 \sigma_+),$$

where $f' = 2 f^2$ and $g' = 2 f^2$.
which yields a system of differential equations, solved to Eqs. (6) and (7). In a similar way one can prove
\[
\begin{align*}
  e^{L_{\pm}z} & = e^{i z a^\dagger} e^{z a} e^{i z a^\dagger} e^{z a}, \\
  e^{L_{+}z} & = e^{i \frac{z^2}{2} a^\dagger} e^{-z a} e^{i \frac{z^2}{2} a^\dagger} e^{-z a}.
\end{align*}
\] (A7) (A8)

The difference between the two sets appears clearly, the propagator \( U_+ \) is compact while \( U_- \) is noncompact, which will correspond to very different physical situations. Now we give some examples of the particular realizations of these systems

\[
\begin{array}{ccc}
  \sigma_+ & \sigma_- & \sigma_z \\
  a & b \dagger & b^\dagger a - a^\dagger a \\
  \frac{1}{2}a^2 & -\frac{1}{2}a^2 & a^\dagger a + \frac{1}{2} \\
  a^\dagger b & -a b & 1 + a^\dagger a + b^\dagger b.
\end{array}
\]

The first case is the Schwinger representation of the spin group that describes the interaction of modes \( a \) and \( b \) on a beam splitter and belongs to the compact \( U_- \) class. The second and the third cases are in the \( U_+ \) class and correspond to the spontaneous emission driven by a classical pump laser.

**APPENDIX B: PROJECTORS IN FOCK SPACE**

Given a quantum state \( \rho = \sum \rho_{nm} |n\rangle \langle m| \) with the mode \( a \) expressed in the Fock space components, we introduce the operators \( \Pi(z) = e^{za^\dagger a} \) and \( \hat{N}(k) = e^{ka^\dagger a} \) with resulting characteristic functions
\[
\begin{align*}
  \Pi(z) & = \text{tr} \rho \, e^{za^\dagger a}, \\
  N(k) & = \text{tr} \rho \, e^{ka^\dagger a},
\end{align*}
\] (B1) (B2)

that are related via \( N(k) = \Pi(e^k) \). The first function is useful to derive projections of the state on Fock components that can describe the perfect detection process
\[
\begin{align*}
  \frac{1}{n!} \delta_n^0 \Pi(z) \bigg|_{z=0} & = \rho_{nn}, \\
  \frac{1}{n!} \delta_n^0 \Pi(z) \bigg|_{z=0} & = \sum_{k \geq 0} \rho_{kk}.
\end{align*}
\] (B3) (B4)

that are projections of the state on \( |n\rangle |n| \) and \( \sum_k |k\rangle \langle k| \), respectively. The second function \( N(k) \) gives mean values of the powers of the number of particles operator
\[
\delta_n^0 N(k) \big|_{k=0} = \text{tr} \rho (a^\dagger a)^n.
\] (B5)

It also can be used to express higher-order correlation functions through \( e^{ka^\dagger a} = :e^{(a^\dagger - 1)ka^\dagger a}: \). Given one of these scalar functions one can extract all the information about the diagonal terms of the density matrix.

**APPENDIX C: ARRAY OF SINGLE-PHOTON DETECTORS**

Consider an array of \( N \) ideal single-photon detectors, if \( N \) is a power of 2 this may be realized with some 50% beam splitters as shown in Fig. 9. However, this restriction is not necessary, all we need is for all detectors to be the same. Now one may define a “see” event by all events when at least \( \theta \) detectors click. The other “not see” case happens when only less than \( \theta \) detectors click given by the operator
\[
\hat{P}_\theta \rho \approx \sum_{j>0} \hat{P}_j,
\] (C1)

where \( \hat{P}_j \) stands for an event where exactly \( j \) detectors click and it is equal to
\[
\hat{P}_j = C^N_j (1 - |0\rangle \langle 0|)^{\theta-j} \otimes |0\rangle \langle 0|^{N-j},
\] (C2)

where \( C^N_j \) corresponds to the number of ways of picking \( j \) detectors out of \( N \). Expand the last expression
\[
\hat{P}_j = \sum_{k \geq 0} C_j^k C^N_{j+k} (-1)^{j-k} |0\rangle \langle 0|^{N-k}.
\]

The projector \( |0\rangle \langle 0|^{N-k} \) describes the event when \( N-k \) detectors don’t get any photons thus all the \( a^\dagger a \) photons go into \( k \) other detectors, the probability of such an event is \( (\frac{x}{N})^{a^\dagger a} \). If we now take the limit \( N \to \infty \) and apply the Stirling approximation to \( C^N_j \), Eq. (C2) becomes
\[
\hat{P}_j = \lim_{N \to \infty} \sum_{k \geq 0} \frac{(-1)^{j-k} k^{a^\dagger a}}{j!(j-k)!} N^{j-a^\dagger a}.
\] (C3)

This expression is obviously zero for \( a^\dagger a > j \), while in the other case we will show in the Appendix that
\[
\sum_{k \geq 0} \frac{(-1)^{j-k} k^{a^\dagger a}}{j!(j-k)!} = \delta_{a^\dagger a}^j, \quad a^\dagger a \leq j,
\] (C4)

yielding \( \lim_{N \to \infty} \hat{P}_j = \delta_{a^\dagger a}^j \) which implies that the limit \( N \) goes to infinity
\[
\hat{P}_\theta \rho \approx \sum_{j \geq 0} \delta_{a^\dagger a}^j = \sum_{j \geq 0} |j\rangle \langle j|, \quad \theta
\] (C5)

to account for a finite efficiency of the detectors we add a loss as in the previous section.

**APPENDIX D: UNIVERSAL CLONING WITH DOPED FIBERS**

Suppose a dipole (two-level system) oriented along a certain direction and coupled resonantly to an optical mode \( a_\beta \), with the polarization being the projection of the dipole orientation on the plane defined by the \( k \) vector. The atom is in the excited state in the plane defined by the \( k \) vector. The atom is in the excited state in the plane defined by the \( k \) vector.
the rotating wave approximation is $H_t = \kappa i (a_\beta^\dagger a_\sigma^\dagger - a_\beta a_\sigma)$ with the propagator being $U_{\beta} = \exp(-i H t)$, because we are dealing with a two-level system with $\sigma^2 = \sigma^+_\perp = 0$ and
\begin{equation}
(a_\beta^\dagger a_\sigma - a_\beta a_\sigma^\dagger)^{2n} = (-1)^n ((a_\beta^\dagger a_\sigma^\dagger)^n |g\rangle\langle g| + (a_\beta a_\sigma)^n |e\rangle\langle e|),
\end{equation}
\begin{equation}
(a_\beta^\dagger a_\sigma - a_\beta a_\sigma^\dagger)^{n+1} = (-1)^n ((a_\beta^\dagger a_\sigma^\dagger)^n a_\beta^\dagger a_\sigma - (a_\beta a_\sigma^\dagger)^n a_\beta a_\sigma^\dagger),
\end{equation}
the exponential can be expanded and resummed yielding
\begin{align}
U_{\beta} &= \cos(\kappa t \sqrt{a_\beta^\dagger a_\beta}) |g\rangle\langle g| + \cos(\kappa t \sqrt{a_\beta a_\beta^\dagger}) |e\rangle\langle e|
+ \frac{\sin(\kappa t \sqrt{a_\beta^\dagger a_\beta})}{\sqrt{a_\beta^\dagger a_\beta}} a_\beta^\dagger a_\sigma - \frac{\sin(\kappa t \sqrt{a_\beta a_\beta^\dagger})}{\sqrt{a_\beta a_\beta^\dagger}} a_\beta a_\sigma^\dagger.
\end{align}

The interaction of a single atom with a propagating optical mode can be reasonably considered small to the first order, in which case the evolution becomes
\begin{equation}
U_{\beta} = (1 - \delta g \frac{\kappa}{2} a_\beta^\dagger a_\beta) |g\rangle\langle g| + (1 - \delta g \frac{\kappa}{2} a_\beta a_\beta^\dagger) |e\rangle\langle e|
+ \sqrt{\delta g a_\beta^\dagger a_\sigma} - \sqrt{\delta g a_\beta a_\sigma^\dagger},
\end{equation}
with $\delta g$ the small interaction parameter. If in the neighborhood of the dipole “$\beta$” there is a dipole oriented in an orthogonal way “$\beta_\perp$” that couples to the orthogonal polarization, we should add the term $U_{\beta_\perp}$ to the evolution operator. Finally, after tracing over the atoms in the exited states the optical state becomes
\begin{equation}
\rho(g + \delta g) = \text{tr}_{\beta, \beta_\perp} U_{\beta} U_{\beta_\perp} \rho(g) \otimes |e\rangle\langle e| \otimes |e\rangle\langle e| U_{\beta}^\dagger U_{\beta_\perp}^\dagger,
\end{equation}
in the limit $\delta g \to 0$ that defines a differential equation
\begin{equation}
\dot{\rho} = -\frac{1}{2} (a a^\dagger \rho + \rho a^\dagger a - 2 a^\dagger \rho a + a a^\dagger \rho
+ \rho a a^\dagger - 2 a^\dagger \rho a).
\end{equation}
Because this expression is invariant we did not write $\beta$, we recovered the universal symmetry. One can easily check that the solution has the form $\mathcal{S}_A(\rho_0)$ defined in Eq. (3).
