Random phase approximation study of one-dimensional fermions after a quantum quench

LANCASTER, Jarrett, GIAMARCHI, Thierry, MITRA, Aditi

Abstract

The effect of interactions on a system of fermions that are in a nonequilibrium steady state due to a quantum quench is studied employing the random phase approximation. As a result of the quench, the distribution function of the fermions is greatly broadened. This gives rise to an enhanced particle-hole spectrum and overdamped collective modes for attractive interactions between fermions. On the other hand, for repulsive interactions, an undamped mode above the particle-hole continuum survives. The sensitivity of the result to the nature of the nonequilibrium steady state is explored by also considering a quench that produces a current-carrying steady state.

I. INTRODUCTION

Recent remarkable experiments1 with cold atoms have motivated an explosion of theoretical interest in the area of nonequilibrium quantum dynamics, with a focus on addressing fundamental questions about thermalization, chaos, and integrability, issues that are very relevant to these experimental systems. Without many general results on generic nonequilibrium phenomena, the analysis of specific, tractable models is a common way to make progress. One hopes clues gathered from these specific systems will lead to more general predictions.

One-dimensional (1D) systems are where much of the theoretical work has taken place since a wide array of tools is available for investigating dynamics. An interesting class of these systems is integrable models, where conserved quantities tightly constrain the time evolution. While a consensus is lacking on a rigorous definition of quantum integrability, progress has been made using many quantum models satisfying classical notions of integrability. Fruitful studies have investigated dynamics of Bethe-ansatz solvable models, but the simplest integrable models are the quadratic ones. These effectively noninteracting theories, including those considered in this paper, allow for exact analytical treatment of the nontrivial dynamics. In 1D, efficient numerical studies are also possible with the time-dependent density matrix renormalization group (TDMRG) and exact diagonalization studies of finite systems.

Some of the analytical and numerical studies have revealed that 1D systems after a quantum quench often reach athermal steady states which can be characterized by a generalized Gibbs ensemble (GGE) constructed from identifying the conserved quantities of the system. There are also many counterexamples where such a description fails, as not all physical quantities can be described using the GGE. One important question concerns the stability of these athermal steady states generated after a quantum quench to other perturbations such as nontrivial interactions that introduce mode coupling and/or the breaking of integrability. Precisely this question was addressed recently in Ref. 21. In particular an initial interaction quench in a Luttinger liquid gives rise to an athermal steady state characterized by new power-law exponents, which can also be captured using a GGE. The effect of mode coupling arising due to a periodic potential on this nonequilibrium state was studied in Ref. 21 using perturbative renormalization group. The analysis revealed that infinitesimally small perturbations can generate not only an effective temperature but also a dissipation or a finite lifetime of the bosonic modes. While the appearance of an effective temperature, although highly nontrivial in itself, can be rationalized on the grounds that a system after a quench is in a highly excited state, and that interactions between particles will somehow cause the system to “thermalize,” the appearance of dissipation is an unexpected and nontrivial result. Thus one of the motivations of the current paper is to identify other physical situations where this dissipation might appear, and to try to investigate the physical mechanisms that could be behind it. Due to the close parallels between interacting bosons and fermions in 1D, a natural candidate for analyzing this question is a one-dimensional system of free fermions that is in a nonequilibrium steady state after a quench. We analyze the effect of weak interactions on this system by employing the random phase approximation (RPA).

In equilibrium, 1D systems are the ideal playground for invoking the RPA. It is an exact low-energy treatment of weak interactions in 1D. In particular, by applying the RPA to a 1D system of electrons, one recovers the standard bosonization of the model, described by a Luttinger liquid. Note that this direct equivalence only holds for the long-wavelength properties, while other excitations require more sophisticated methods such as bosonization. While the accuracy of the RPA in 1D is known in equilibrium, its applicability out of equilibrium is not guaranteed. In the type of quench problem considered here, the initial state has nonzero overlap with excited eigenstates of the Hamiltonian generating time evolution. It is far from certain that a low-energy description captures all the important physics. While this caveat leads to intriguing, unanswered questions, in this paper we will use the RPA as an approximation scheme and will not address the deeper question of its potential breakdown out of equilibrium.

In this paper, we thus apply the RPA to a nonequilibrium state in theXXZ spin chain. This state is prepared as follows. The system is initially in the ground state of an exactly
solvable Hamiltonian \( \mathcal{H} \). We choose two different models for \( \mathcal{H} \), one corresponding to the transverse-field Ising model with the magnetic field tuned to the critical value where the spectrum is gapless, and the second the same as above but with an additional Dzyaloshinskii-Moriya interaction added.

A quantum quench is then performed by switching off the field and changing the exchange anisotropy so that the time evolution is due to the XX model. Since this model is described by free fermions, at long times after the quench, the system reaches an athermal steady state characterized by a GGE. For \( \mathcal{H} \) that has Dzyaloshinskii-Moriya interactions, the steady state is qualitatively different in that it carries a net current. We then ask how these athermal steady states are affected by the magnetic field tuned to the critical value where the system is critical.33 The ground state is defined by \( \sum_j \hat{S}_j^z = 0 \) which is qualitatively different in that it carries a net current.

By free fermions, at long times after the quench, the system is critical.33 The ground state is defined by \( \sum_j \hat{S}_j^z = 0 \) which is qualitatively different in that it carries a net current. We then ask how these athermal steady states are affected by the magnetic field tuned to the critical value where the system is critical.33 The ground state is defined by \( \sum_j \hat{S}_j^z = 0 \) which is qualitatively different in that it carries a net current.

The model is considered. In Sec.IV the RPA involving fermions will be studied and the notations and conventions are defined. In Sec.V the RPA involving fermions in a current-carrying steady state is presented, and in Sec.V the RPA involving fermions in a current-carrying steady state is presented, and in Sec.V we summarize our results.

II. MODEL

Below we describe the two different quenches which lead to nonequilibrium steady states without (Sec. II A) and with (Sec. II B) currents.

A. Quench from ground state

The XY spin chain in a magnetic field is defined as

\[
\hat{H}_t = -J \sum_j \left[ (1 + \gamma) \hat{S}_j^x \hat{S}_{j+1}^x + (1 - \gamma) \hat{S}_j^y \hat{S}_{j+1}^y \right] + \hbar \sum_j \hat{S}_j^z,
\]

where \( \gamma = 1 \) corresponds to the transverse-field Ising model. The XY model has been extensively studied,28–30 and its equilibrium properties are well understood. It is also a popular model16,31,32 for studying nonequilibrium situations due to its simple mapping to free fermions. Writing this Hamiltonian in terms of Jordan-Wigner fermions,

\[
\hat{S}_j^+ = c_j^\dagger \exp \left[ i \pi \sum_{n<j} c_n^\dagger c_n \right],
\]

\[
\hat{S}_j^- = \exp \left[ -i \pi \sum_{n<j} c_n^\dagger c_n \right] c_j,
\]

we obtain

\[
\hat{H}_t = -\frac{J}{2} \sum_j \left[ c_j^\dagger c_{j+1}^\dagger + c_{j+1} c_j + \gamma c_j^\dagger c_{j+1}^\dagger + \gamma c_{j+1} c_j \right]
+ \hbar \sum_j c_j^\dagger c_j.
\]

This is diagonalized by a Bogoliubov rotation29

\[
\hat{H}_t = \sum_k \epsilon_k \eta_k^\dagger \eta_k,
\]

where

\[
\epsilon_k^\dagger = -J \frac{\cos k - \hbar/\gamma}{\sqrt{(\cos k - \hbar/\gamma)^2 + \gamma^2 \sin^2 k}},
\]

and

\[
\begin{pmatrix}
\cos \frac{\theta_k}{2} & i \sin \frac{\theta_k}{2} \\
-i \sin \frac{\theta_k}{2} & \cos \frac{\theta_k}{2}
\end{pmatrix}
\begin{pmatrix}
\eta_k \\
\eta_{-k}
\end{pmatrix}.
\]

with

\[
\cos \theta_k = \frac{|\cos k - (\hbar/\gamma)|}{\sqrt{(\cos k - \hbar/\gamma)^2 + \gamma^2 \sin^2 k}},
\]

\[
\sin \theta_k = \frac{\text{sgn}[\cos k - (\hbar/\gamma)] \gamma \sin k}{\sqrt{(\cos k - \hbar/\gamma)^2 + \gamma^2 \sin^2 k}}.
\]

Here \( c_j = \frac{1}{\sqrt{N}} \sum_k c_k \). The ground state is obtained by occupying all modes with negative energy. We will be interested in the special case of \( \gamma = \hbar/J = 1 \), where the system is critical.33 The ground state is defined by \( \eta_k |\Phi_0\rangle = 0 \) for all k, as \( \epsilon_k^\dagger = 2J |\sin \frac{\theta_k}{2}| \) is always non-negative.
Given this initial state, we perform the quench by suddenly switching off the anisotropy $\gamma$ and magnetic field $h$. The subsequent time evolution is due to the $XX$ Hamiltonian,

$$\hat{H}_{XX} = -J \sum_j \left[ \hat{S}_j^x \hat{S}_{j+1}^x + \hat{S}_j^y \hat{S}_{j+1}^y \right]$$

$$= \sum_k \epsilon_k c_k^\dagger c_k,$$  \hspace{1cm} (12)

where $\epsilon_k = -J \cos k$ and the $c_k$ are the momentum-space Jordan-Wigner fermions defined above. At long times after the quench, the system approaches a diagonal ensemble. To see this, note that immediately after the quench, the following quantities are fixed by the initial state:

$$\langle c_k^\dagger c_k \rangle_0 = \cos^2 \frac{\theta_k}{2} \langle \eta_k^1 \eta_k^1 \rangle + \sin^2 \frac{\theta_k}{2} \langle \eta_k^1 \eta_{-k}^1 \rangle,$$  \hspace{1cm} (13)

$$\langle c_k c_{-k} \rangle_0 = i \sin \frac{\theta_k}{2} \cos \frac{\theta_k}{2} \left[ \langle \eta_k^1 \eta_{-k}^1 \rangle - \langle \eta_k^1 \eta_{-k}^1 \rangle \right].$$  \hspace{1cm} (14)

The time evolution of the $c$ operators takes the simple form $c_k(t) = e^{-i\epsilon_k t} c_k$. One finds

$$\langle c_k^\dagger(t) c_k(t) \rangle = \langle c_k^\dagger c_k \rangle_0,$$  \hspace{1cm} (15)

$$\langle c_k(t) c_{-k}(t) \rangle = e^{-2i\epsilon_k t} \langle c_k c_{-k} \rangle_0.$$  \hspace{1cm} (16)

When averaged over long times,

$$\frac{1}{t_b - t_a} \int_{t_a}^{t_b} dt \langle c_k c_{-k}(t) \rangle \to 0$$

for $(t_b - t_a) \to \infty$, due to the rapidly oscillating exponential. Thus we obtain a diagonal ensemble in the long-time limit with a highly broadened momentum distribution given by

$$\langle c_k^\dagger c_k \rangle_0 = \frac{1}{2} \left( 1 - \frac{1}{2} \sec \frac{k}{2} \right).$$  \hspace{1cm} (18)

Note that, as we discuss at the end of this section, such an approximation is not necessary and one can retain the oscillating modes. However, it considerably simplifies the expressions to explicitly eliminate them. By equating the above nonequilibrium distribution function to a Fermi function, one may define a (momentum-dependent) effective temperature

$$T_{\text{eff}} = \frac{1}{J} \cos k \left[ \frac{1 + | \sin \frac{k}{2} |}{1 - | \sin \frac{k}{2} |} \right]^{-1},$$

(19)

where one notes $T_{\text{eff}} < 0$ for $k < \pi / 2$. As we shall see later, since the system is out of equilibrium, this temperature is not universal, but depends on the quantity being studied.

Once the above steady state has been reached, we consider the effect of nearest-neighbor Ising interactions in the $XXZ$ model,

$$\hat{H}_J = \hat{H}_{XX} + J \sum_j \hat{S}_j^x \hat{S}_{j+1}^x,$$  \hspace{1cm} (20)

where we assume that $J^z$ was switched on very slowly, so that in the absence of a quench, the fermions will evolve into the ground state of the $XXZ$ chain. The effects of this interaction term will be treated within the RPA.

The basic fermionic Green’s functions defined by

$$G^R_f(k; t, t') = -i \theta(t - t') \langle c_k(t) c_k^\dagger(t') \rangle,$$  \hspace{1cm} (21)

$$G^K_f(k; t, t') = -i \langle c_k(t) c_k^\dagger(t') \rangle$$

are found to be

$$G^R_f(k; t, t') = -i \theta(t - t') e^{-i\epsilon_k(t-t')},$$  \hspace{1cm} (23)

$$G^K_f(k; t, t') = -i e^{-i\epsilon_k(t-t')} \sin \frac{k}{2} \frac{\sin(\epsilon_k t)}{k}.\hspace{1cm} (24)$$

Within the RPA, the particle-hole bubbles are\(^{35}\)

$$\Pi^R(1,2) = \frac{-i}{2} \left[ G^R_f(1,2) G^K_f(2,1) \right. \left. + G^K_f(1,2) G^K_f(2,1) \right]$$

(25)

In momentum space they are given by

$$\Pi^R(q, \omega) = \frac{-i}{2} \int \frac{dk}{2\pi} \frac{d\Omega}{2\pi} \left[ G^R_f(k + q, \omega + \Omega) G^K_f(k, \Omega) \right.$$

$$\left. + G^K_f(k + q, \omega + \Omega) G^K_f(k, \Omega) \right.$$

(26)

$$\left. + G^K_f(k + q, \omega + \Omega) G^K_f(k, \Omega) \right].$$

The collective mode dispersion is defined by the roots of the complex dielectric function,\(^{37}\)

$$\epsilon_{\text{RPA}}(q, \omega) = 1 - V_q \Pi^R(q, \omega) = 0,$$  \hspace{1cm} (29)

where we neglect the $q$ dependence of $V_q$ and take it to be $V_q = J^z \equiv V_0$. The RPA analysis is given in Sec. III.

As mentioned above, it is not critical to work with the diagonal ensemble. If we had retained the full time dependence in Eq. (16), the integration over the internal $k$ variable in the evaluation of the RPA bubbles would result in terms that decay with time. Since we are ultimately interested in the long-time limit, these contributions are not important for us.

**B. Quench resulting in a current-carrying state**

We will also be interested in how the collective dynamics change when the athermal steady state is characterized by a net current. This is generated by adding a Dzyaloshinskii-Moriya interaction term\(^{36}\) to the $XY$ model, $\hat{H}_J \rightarrow \hat{H}_J + \hat{H}_{DM}$, where

$$\hat{H}_{DM} = -\lambda \sum_j \left[ \hat{S}_j^x \hat{S}_{j+1}^z - \hat{S}_j^z \hat{S}_{j+1}^x \right].$$

(30)

This new Hamiltonian is diagonalized by the same Bogoliubov rotation\(^{37,38}\) that diagonalizes the pure $XY$ model. In the isotropic case ($XX$ chain), this can be interpreted as a spatially dependent, physical rotation of the spins.\(^{39,40}\) For
the more general anisotropic chain, the spectrum is similarly modified,\textsuperscript{37,41}

\[ \hat{H}_f(\lambda) = \sum_k \epsilon'_k \eta_k^\dagger \eta_k, \]

\[ \epsilon'_k = \epsilon_k' - \lambda \sin k, \]

with \( \epsilon'_k \) given in Eq. (7), \( \lambda \) has the effect of raising the energies of states with \( k < 0 \) while lowering the energies of modes with positive \( k \). The occupation number is now nonzero for \( \lambda > J \), and the \( \eta \)-fermion occupation is \( n_k \equiv \langle \eta_k^\dagger \eta_k \rangle = \theta(k)\theta(k_0 - k) \), with

\[ k_0 = 2 \cos^{-1} \left( \frac{J}{\lambda} \right). \]

We will see in Sec. IV that the presence of this nonzero “Fermi momentum” will give rise to multiple damped modes within the particle-hole continuum that are not present for the zero-current steady state. Furthermore, above a certain critical filling factor the single undamped collective mode will cease to exist.

The asymmetry in momentum space drives a current in the modified ground state given by

\[ \langle j_n \rangle = J \text{Im} \langle \hat{S}_{n+1}^z \hat{S}_{n}^z \rangle = \begin{cases} 0 & (\lambda < J), \\ \frac{\theta(k)\theta(k_0 - k)}{2} \left[ 1 + \left( \frac{\sin k}{2} \right)^2 \right] & (\lambda > J). \end{cases} \]

It should be noted that this operator can be interpreted as the current operator only within the XX model where the total magnetization commutes with the Hamiltonian.

Performing a quench where \( \lambda, h, \) and \( \gamma \) are switched off allows this state to evolve under the XX model, obtaining a nonequilibrium momentum distribution

\[ \langle c_k^\dagger c_k \rangle_0 = \frac{1}{2} \left( 1 - \left| \sin \frac{k}{2} \right|^2 \right) + \frac{\theta(k)\theta(k_0 - k)}{2} \left[ 1 + \left( \frac{\sin k}{2} \right)^2 \right] - \frac{\theta(-k)\theta(k_0 + k)}{2} \left[ 1 - \left( \frac{\sin k}{2} \right)^2 \right] \]

and a current given by Eq. (34). The distribution function for several different current strengths is shown in Fig. 1.

After the decay of transients \( \langle c_k^\dagger c_{-k} \rangle \) and \( \langle c_k^\dagger c_{-k}^\dagger \rangle \), we investigate the collective modes by employing the RPA analysis outlined in Sec. III A. The RPA requires knowledge of the single-particle Green’s functions. The presence of a current does not affect the retarded Green’s function [Eq. (23)], but modifies the Keldysh Green’s function as follows:

\[ G^R_f(k; t, t') = -ie^{-ik(t-t')} \begin{pmatrix} \left| \sin \frac{k}{2} \right| (1 - n_k - n_{-k}) \\ (n_k - n_{-k}) \end{pmatrix}, \]

where \( n_k = \theta(k)\theta(k_0 - k) \) is the occupation number of the \( \eta \) fermions in the initial state.

III. RPA FOR QUENCH FROM GROUND STATE

In this section, we investigate the effect of interactions on the athermal steady state (Sec. III A) obtained from quenching from the ground state of the transverse-field Ising model. The RPA particle-hole bubbles are

\[ \Pi^R(q, \omega) = -\frac{1}{2} \int \frac{dk}{2\pi} \frac{\cos \theta(1 - 2n_k)}{(\omega + i\delta + \epsilon_k - \epsilon_{k+q})} - \frac{\cos \theta_{k+q}(1 - 2n_{k+q})}{(\omega + i\delta + \epsilon_k - \epsilon_{k+q})}, \]

\[ \Pi^K(q, \omega) = \frac{i}{2} (2\pi)^2 \int \frac{dk}{2\pi} \delta(\omega + \epsilon_k - \epsilon_{k+q}) \times [\cos \theta_k \cos \theta_{k+q}(1 - 2n_k)(1 - 2n_{k+q}) - 1]. \]

For the case of interest, \( \gamma = h/J = 1 \), we have \( \cos \theta_k = |\sin \frac{k}{2}| \), and the distribution of the \( \eta \) fermions \( n_k = 0 \).

There are some basic symmetries of the polarization bubbles that are worth mentioning. First \( \Pi^{R,K}(q, \omega) = \Pi^{R,K}(-q, \omega) \), while \( \text{Re}[\Pi^R(q, -\omega)] = \text{Re}[\Pi^R(q, \omega)] \), \( \Pi^K(q, -\omega) = \Pi^K(q, \omega) \), and \( \text{Im}[\Pi^R(q, -\omega)] = -\text{Im}[\Pi^R(q, \omega)] \). Therefore in what follows we will assume \( q > 0, \omega > 0 \), and the results for the other regimes can be extrapolated from the above symmetries.

There are two regimes which we will study separately. One is \( \omega > 2J \sin \frac{k}{2} \), where \( \text{Im}[\Pi^R] = \Pi^K = 0 \), and the other is \( \omega < 2J \sin \frac{k}{2} \), where \( \text{Im}[\Pi^R] \neq 0, \Pi^K \neq 0 \).

A. Evaluation for \( \omega > 2J \sin \frac{k}{2} \)

In this regime, the integrand contains no poles, and the result is purely real: \( \text{Re}[\Pi^R(q, \omega)] = \Pi^K(q, \omega) \) and \( \text{Im}[\Pi^R(q, \omega)] = 0 \). One may safely take \( \delta \to 0 \) to find

\[ \Pi^R(q, \omega) = \frac{1}{2\pi i} \frac{-\cos \frac{q}{2}}{\sqrt{\omega^2 - (2J \sin \frac{k}{2})^2}} \left\{ z_+ \ln \left[ \frac{1 + \sin \frac{q}{2}}{1 - \sin \frac{q}{2}} \right] \right. \]

\[- z_- \ln \left[ \frac{1 + \sin \frac{q}{2}}{1 - \sin \frac{q}{2}} \right] \] \times \left\{ z_+ \ln \left[ \frac{1 + \cos \frac{q}{2}}{1 - \cos \frac{q}{2}} \right] - z_- \ln \left[ \frac{1 + \cos \frac{q}{2}}{1 - \cos \frac{q}{2}} \right] \right\}, \]

\[ (39) \]
with

$$z_k^2 = \frac{1}{2} \pm \frac{1}{2} \sqrt{1 - \left(\frac{\omega}{2J \sin \frac{q}{2}}\right)^2} \quad \forall \omega < 2J \sin \frac{q}{2}$$

$$= \frac{1}{2} \pm \frac{i}{2} \sqrt{\left(\frac{\omega}{2J \sin \frac{q}{2}}\right)^2 - 1} \quad \forall \omega > 2J \sin \frac{q}{2}. \quad (40)$$

Note that our convention is to place the branch cut of the logarithm on the negative real axis. In this same regime of $\omega > 2J \sin \frac{q}{2}$ there are no roots to the argument of the $\delta$ function in the Keldysh component, and we have \(\Pi^K(q,\omega) = 0\). With \(\Pi^K(q,\omega)\) purely real, this regime lies outside the particle-hole continuum. In Sec. III C we will demonstrate the existence of an undamped collective mode lying just above the particle-hole continuum for repulsive interactions only.

B. Evaluation for $\omega < 2J \sin \frac{q}{2}$

For $\omega < 2J \sin \frac{q}{2}$ the integrand generically contains poles. We extract the real and imaginary parts in the usual way by writing

$$\int \frac{dk}{2\pi} \frac{f(k)}{\omega + i\delta + \epsilon_k - \epsilon_{k+q}} = \int \frac{dk}{2\pi} P \left( \frac{f(k)}{\omega + \epsilon_k - \epsilon_{k+q}} \right) - i\pi \int \frac{dk}{2\pi} f(k) \delta(\omega + \epsilon_k - \epsilon_{k+q}) \quad (41)$$

$$\equiv \text{Re}[\Pi^K] + i\text{Im}[\Pi^K], \quad (42)$$

where $P$ denotes taking the principal value of the integral. We obtain

$$\text{Re}[\Pi^K(q,\omega)] = \frac{-\cos \frac{q}{2}}{2\pi \sqrt{(2J \sin \frac{q}{2})^2 - \omega^2}} \times \left\{ z_+ \ln \frac{1 + \sin \frac{q}{2}}{1 - \sin \frac{q}{2}} - z_- \ln \frac{1 + \sin \frac{q}{2}}{1 - \sin \frac{q}{2}} \right\} \quad (43)$$

$$+ \frac{\sin \frac{q}{2}}{2\pi \sqrt{(2J \sin \frac{q}{2})^2 - \omega^2}} \times \left\{ z_+ \ln \frac{1 + \cos \frac{q}{2}}{1 - \cos \frac{q}{2}} - z_- \ln \frac{1 + \cos \frac{q}{2}}{1 - \cos \frac{q}{2}} \right\}$$

with $z_{\pm}$ defined in Eq. (40). The results for the imaginary part $\text{Im}[\Pi^K] = \frac{\Pi^K - \Pi^K^*}{2i}$ and the Keldysh component subdivide the particle-hole continuum into two subregions, $0 < \omega < 2J \sin^2 \frac{q}{2}$ and $2J \sin^2 \frac{q}{2} < \omega < 2J \sin \frac{q}{2}$.

For $0 < \omega < 2J \sin^2 \frac{q}{2}$ one finds

$$\text{Im}[\Pi^K(q,\omega)] = \frac{-1}{2\pi \sqrt{(2J \sin \frac{q}{2})^2 - \omega^2}} \Bigg[ \left( \cos \frac{q}{4} + \sin \frac{q}{4} \right) \times \sin \left( \frac{1}{2} \sin^{-1} \frac{\omega}{2J \sin \frac{q}{2}} \right) \Bigg]. \quad (44)$$

The particle-hole continuum, which is the region in $\omega, q$ space where $\text{Im}[\Pi^K] \neq 0$ is indicated as the shaded region in Fig. 2 and compared with the equilibrium (no-quench) result (inset). The two different shadings refer to the discontinuity in the functional forms of $\text{Im}[\Pi^K, \Pi^K]$ across $\omega = 2J \sin^2 \frac{q}{2}$. The consequences of these results are discussed below.

C. Undamped mode for $\omega > 2J \sin \frac{q}{2}$ and $V_0 > 0$

The undamped mode is obtained from the solution of

$$1 - V_0 \Pi^K(q,\omega) = 0 \quad (48)$$

with $\Pi^K(q,\omega)$ given in Eq. (39). For sufficiently small $V_0$, we need to identify the points where $\Pi^K$ diverges. This occurs for $\omega = 2J \sin(q/2)$. Thus in the limit of $\omega \rightarrow 2J \sin \frac{q}{2}$, we can write $z_{\pm} = \sqrt{\frac{1}{2}}(1 \pm \frac{\epsilon}{2J \sin \frac{q}{2}})$ with $\epsilon = \sqrt{\omega^2 - (2J \sin \frac{q}{2})^2}$. The
dominant contribution assuming that $q \to 0$ (so that $\cos \frac{2}{3} \approx 1$) is given by
\[
\Pi^R(q,\omega) \simeq -\frac{\sin \frac{q}{2}}{2\pi i \sqrt{\omega^2 - (2J \sin \frac{q}{2})^2}}.
\]

Due to the branch cut in the logarithm (chosen to be on the negative real axis), in the limit $\epsilon \to 0$, the above expression can be further simplified to give
\[
\Pi^R(q,\omega) \simeq -\frac{\sin \frac{q}{2}}{\sqrt{\omega^2 - (2J \sin \frac{q}{2})^2}}.
\]

Thus from Eq. (48) we find a single undamped mode provided $V_0$ is positive with a dispersion
\[
\omega_q \simeq \theta(V_0)|q|\sqrt{1 + \frac{V_0^2}{32J^2}}.
\]

This can be compared to the undamped mode in the equilibrium problem,
\[
\omega_q^{\text{eq}} \simeq |q|\sqrt{1 + \frac{V_0}{\pi J}}.
\]

This excitation energy depends not only on the momentum of the excitation, but also on the momentum of the original particle, $k$. For a half-filled band at zero temperature, the occupation of fermions is $(\epsilon_k \epsilon_k)_{\text{eq}} = \theta(\frac{\pi}{2} - |k|)$. The only momenta available for hole creation are those with $|k| < k_F = \frac{\pi}{2}$. Because the cosine dispersion has maximal slope at $k = \frac{\pi}{2}$, the maximum excitation energy occurs for a given $q$ with $k = \frac{\pi}{2} - \frac{q}{2}$. The smallest excitation energy for a given $q$ at zero temperature occurs at $k = \frac{\pi}{2}$ or $k = \frac{\pi}{2} - q$. Thus
\[
\omega_{\text{max}}(q) = \omega\left(\frac{\pi}{2} - \frac{q}{2}\right) = 2J \sin \frac{q}{2},
\]
and
\[
\omega_{\text{min}}(q) = \omega\left(\frac{\pi}{2}, q\right) = J \sin q,
\]
which are just the upper and lower boundaries of the particle-hole continuum (inset of Fig. 2). Now, consider lowering $k_F$. Excitations of smaller energy for a given $q$ are now possible, and in the limit $k_F \to 0$, we have $\omega_{\text{min}} \to 2J \sin^2 \frac{q}{2}$. The result is the same if one considers the opposite limit of $k_F \to \pi$ at zero temperature.

In the present nonequilibrium situation, we find a particle-hole continuum ($\text{Im}[\Pi^R(q,\omega)] \neq 0$) that extends below this lower bound all the way to $\omega = 0$. A finite temperature is known to smear out this lower boundary due to the smoothing out of the zero-temperature step function for the occupation probability. It is interesting to note that the expressions for $\text{Im}[\Pi^R(q,\omega)]$ and $\Pi^K(q,\omega)$ are actually continuous across the line $\omega = 2J \sin^2 \frac{q}{2}$, with discontinuities appearing in their derivatives. In Fig. 2 we plot the undamped collective mode dispersion with the particle-hole continuum represented by the shaded region. The two different shadings are separated by the line $\omega = 2J \sin^2 \frac{q}{2}$. The analogous plot for the equilibrium situation is shown in the inset.

IV. RPA FOR CURRENT-CARRYING STATE

We now apply the RPA to study the current-carrying nonequilibrium steady state described in Sec. II B. The Keldysh component of the fermion Green’s function is
\[
iG^K_f(k,t,t') = [\cos \theta_q(1 - n_k - n_{-k}) - \frac{J}{2} (n_k - n_{-k})] e^{-i\omega(t-t')}.
\]
while the retarded Green’s function is given in Eq. (23), and $n_{\pm} = \theta(k) - \theta(k_0 - k)$. Equation (61) implies that the distribution function for the Jordan-Wigner fermions in the current-carrying postquench state is not only broad as for the zero-current case, but is also asymmetric in $k$, with sharp discontinuities superimposed on it (see Fig. 1). Thus we will find that, as for the zero-current case, the particle-hole continuum here too is broadened (extending everywhere below the line $\omega_{\max} = 2J \sin \frac{\theta}{2}$), while the sharp structure in the distribution gives rise to some discontinuities in the expression for $\text{Im}[\Pi^R]$ and the appearance of additional damped modes.

The particle-hole bubbles are now given by

$$
\Pi^R(q, \omega) = -\frac{1}{2} \int \frac{dk}{2\pi} \frac{\cos \theta_k(1 - n_k - n_{-k})}{\omega + i\delta - 2J \sin \frac{\omega}{2} \sin (k + \frac{q}{2})} 
$$

where

$$
\mathcal{F}(z) = z_+ \ln \left[ \frac{1 + \frac{\omega}{2\sin \theta}}{1 - \frac{\omega}{2\sin \theta}} \right] - z_- \ln \left[ \frac{1 + \frac{\omega}{2\sin \theta}}{1 - \frac{\omega}{2\sin \theta}} \right].
$$

In the limit $k_0 \to 0$, we recover the results of Sec. III. The remaining terms can be collected as

$$
\Pi^{(2)}(q, \omega) = \frac{1}{4\pi} \int \frac{dk}{\omega^2 - (2J \sin \frac{\omega}{2})^2} \times \left\{ \ln \left[ 1 + \frac{\omega \tan \left( \frac{\omega}{2\sin \theta} \right)}{4J \sin \frac{\omega}{2} \sin \theta} \right] - \ln \left[ 1 + \frac{\omega \tan \left( \frac{\omega}{2\sin \theta} \right)}{4J \sin \frac{\omega}{2} \sin \theta} \right] \right\},
$$

(62)

As before, two regions appear, one where $\omega > 2J \sin \frac{\theta}{2}$ for which $\text{Im}[\Pi^R] = \Pi^K = 0$, and the second for $\omega < 2J \sin \frac{\theta}{2}$ where a particle-hole continuum is found to exist. We discuss these two regions separately.

### A. Evaluation for $\omega > 2J \sin \frac{\theta}{2}$

In this regime, as before, the result is entirely real and we let $\delta \to 0$. We find it convenient to write $\Pi^R = \Pi^{(1)} + \Pi^{(2)}$, where $\Pi^{(1)}$ depends on the Bogoliubov angle, $\cos \theta_k = |\sin \frac{\omega}{2}|$, while $\Pi^{(2)}$ contains the rest. As before it is convenient to summarize the symmetries of the polarization bubbles. We find $\Pi^{(1)}(q, \omega) = \Pi^{(1)}(q, \omega)$; however, due to current flow, $\Pi^{(2)}(q, \omega) = -\Pi^{(2)}(q, \omega)$. Similarly, $\text{Re}[\Pi^{(1)}(q, \omega)] = \text{Re}[\Pi^{(1)}(q, \omega)]$, while $\text{Re}[\Pi^{(2)}(q, \omega)] = -\text{Re}[\Pi^{(2)}(q, \omega)]$. In the discussion that follows, we take $q > 0, \omega > 0$.

We find

$$
\Pi^{(1)}(q, \omega) = -\frac{\cos \frac{\omega}{2}}{4\pi i \sqrt{(2J \sin \frac{\omega}{2})^2 - \omega^2}} \left\{ \mathcal{F} \left( \sin \left[ \frac{k_0}{2} + \frac{q}{4} \right] \right) + \mathcal{F} \left( \sin \left[ -\frac{k_0}{2} + \frac{q}{4} \right] \right) \right\},
$$

(67)

where

$$
\mathcal{F}(z) = z_+ \ln \left[ \frac{1 + \frac{\omega}{2\sin \theta}}{1 - \frac{\omega}{2\sin \theta}} \right] - z_- \ln \left[ \frac{1 + \frac{\omega}{2\sin \theta}}{1 - \frac{\omega}{2\sin \theta}} \right].
$$

The consequence of the above expressions for $\Pi^{(1,2)}$ will be discussed in Sec. IV C.
and
\[
\text{Re}[\Pi^K(q,\omega)] = -\frac{1}{4\pi \sqrt{(2J \sin \frac{\omega}{2})^2 - \omega^2}}
\times \left\{ \ln \left[ 1 + \frac{\omega \tan \left( \frac{\omega}{2} + \frac{\pi}{2} \right)}{4J \sin \frac{\omega}{2}} \right] - \ln \left[ 1 - \frac{\omega \tan \left( \frac{\omega}{2} + \frac{\pi}{2} \right)}{4J \sin \frac{\omega}{2}} \right] \right\}.
\]

Thus by setting \( 1 - V_0 \Pi^K = 0 \), we recover the same dispersion as in the absence of current,
\[
\omega_q \simeq J |q| \sqrt{1 + \frac{V_0^2}{32J^2} \theta(\theta(\pi/2 - k_0))}.
\]

This, the undamped mode is unchanged for a current which is below the threshold value of \( k_0 < \pi/2 \). On the other hand, for currents larger than this value \( k_0 > \pi/2 \) and for \( q \ll k_0 \), no undamped modes exist.

**D. Damped modes for \( \omega < 2J \sin \frac{\omega}{2} \)**

In this regime, all modes are damped. We identify these damped modes by looking for solutions to \( 1 - V_0 \text{Re}[\Pi^K(q,\omega)] = 0 \). For \( V_0 \to 0 \), all we need to do is identify where \( \text{Re}[\Pi^K] \to \pm \infty \). Then positive divergences correspond to damped modes with repulsive interactions, while negative divergences correspond to damped modes with attractive interactions.

Upon examining Eqs. (68) and (70), we find logarithmic divergences in \( \text{Re}[\Pi^K(q,\omega)] \) along the characteristic lines for \( \omega, q > 0 \)
\[
\omega_1(q) = 2J \sin^2 \frac{q}{2},
\]
\[
\omega_2(q) = 2J \sin \frac{q}{2} \sin \left( k_0 + \frac{q}{2} \right),
\]
\[
\omega_3(q) = \pm 2J \sin \frac{q}{2} \sin \left( \frac{q}{2} - k_0 \right).
\]

Note that \( \omega_{2,3} \) coincide with the characteristic lines in the equilibrium problem with an arbitrary Fermi momentum \( k_0 \). In the equilibrium problem, these lines represent boundaries across which \( \text{Im}[\Pi^K] \) undergoes a jump discontinuity. This is also the case here, although we will focus our attention on the behavior of the real part.

One finds \( \text{Re}[\Pi^K] \to +\infty \) along the line \( \omega_1(q) \) for \( 2k_0 < q < \pi \) and along the line \( \omega_2(q) \) for \( q < \pi - 2k_0 \). These correspond to damped collective modes for repulsive interactions. Furthermore, \( \text{Re}[\Pi^K] \to -\infty \) along the line \( \omega_1(q) \) for all \( q \in (0, \pi) \), along \( \omega_3(q) \) for \( q < 2k_0 \), and along \( \omega_2(q) \) for \( q > \pi - 2k_0 \). These negative divergences represent collective modes created by attractive interactions. We plot these characteristic lines in Fig. 3 and indicate whether the mode exists for attractive or repulsive interactions.

Such damped modes are usually considered physically uninteresting\cite{25} compared to any undamped excitations in the system, as the damping makes these modes experimentally unobservable. The divergences in \( \Pi^K(q,\omega) \) that give rise to these damped modes are of a different nature from those giving rise to the undamped mode. To see this consider the case of \( \omega \simeq \omega_1 = 2J \sin^2 \left( \frac{q}{2} \right) \) for small \( \epsilon \).

The above expression shows that provided \( k_0 < \pi/2 \), which corresponds to the logarithms having a branch cut, we obtain
\[
\Pi^K(q,\omega) = \frac{\sin \frac{\omega}{2}}{\sqrt{2(\omega^2 - (2J \sin \frac{\omega}{2})^2)}}.
\]

The dominant contribution is given by
\[
\text{Re}[\Pi^K(q,\omega)] \simeq -\frac{1}{8\pi J \sin \frac{\omega}{2} \cos \frac{\omega}{2} \left[ 2 \ln \frac{A_q}{\epsilon} \right]},
\]

where \( A_q \) is a \( q \)-dependent factor.
Solving $1 = V_0 \Re[\Pi^R(q, \omega)]$ to leading order in $\epsilon$, one finds

$$\Re[\omega_q] \simeq 2J \sin \frac{q}{2} \left( \sin \frac{q}{2} \pm A_q e^{-(2\pi J \sin q)/|V_0|} \right),$$

where $q > 0$ is assumed. In general, for any of the characteristic lines described above, the ansatz $\omega = \omega_q \pm 2J \epsilon \sin \frac{q}{2}$ leads to a divergence of the form $\Pi^R(q, \omega) \sim \pm \ln \frac{1}{\epsilon}$. Each logarithmic divergence corresponds to two damped modes lying exponentially close to each characteristic line.

One may study the modes near $\omega \approx \omega_2(q)$ in a way similar to our analysis for the modes near $\omega_1$. For $\omega \approx \omega_2(q) \pm 2J \epsilon \sin \frac{q}{2}$, one finds

$$\Re[\Pi^R(q, \omega)] \simeq \frac{1 + \sin \frac{k_0}{2}}{8\pi J \sin \frac{q}{2} \left| \cos \left( \frac{k_0 + q}{2} \right) \right|} \ln \frac{A'_q}{\epsilon},$$

which gives rise to damped modes for repulsive interactions ($V_0 > 0$) when $q < \pi - 2k_0$ with

$$\Re[\omega_q] \simeq 2J \sin \frac{q}{2} \left| \sin \left( \frac{q}{2} + k_0 \right) \right| \pm A'_q \exp \left\{ -\frac{8\pi J \sin \frac{q}{2}}{V_0 \left( 1 + \sin \frac{q}{2} \right)} \right\}.$$  

The result for the other characteristic line $\omega_3^+$ is similar and we do not discuss it further.

**V. SUMMARY AND CONCLUSIONS**

In this paper, we have applied the RPA to study the effect of weak Ising interactions in a nonequilibrium steady state of the XXZ spin chain. This nonequilibrium state was created in two different ways. One was by quenching from the ground state of the transverse-field Ising model at critical magnetic field to the XX model. The second was to modify the Hamiltonian before the quench by adding Dzyaloshinskii-Moriya interactions. This had the effect of creating a current-carrying state.

The RPA for both the steady states shows the existence of a single, undamped, collective mode for repulsive interactions which is qualitatively similar to the sound mode in equilibrium, but with quantitative changes to the mode velocity [see Eq. (51)]. However, if the current is larger than a threshold value, this undamped mode ceases to exist in the long-wavelength limit [see Eq. (74)]. The primary effect of the quench is to give rise to a greatly broadened distribution function [see Fig. 1 and Eq. (35)], which results in an enhanced particle-hole continuum. The boundaries of the particle-hole continuum are shown in Fig. 2. Thus for attractive interactions either no modes are found for the first steady state, or some damped collective modes are found for the steady state with current.

These results, and in particular the generation of a finite friction due to an out-of-equilibrium situation, are rather generic and do not depend on the details of the nonequilibrium steady state. Further, the upper boundary of the particle-hole continuum occurs at $\omega^*_Q = 2J \sin \frac{\pi}{4}$ and is related to the fact that the system is on a lattice, and therefore the excitations have a maximum velocity. If instead a quadratic dispersion for the fermions is adopted, then there is no upper limit to the velocity of excitations. This, together with the fact that immediately after a quench the Fermi distribution is very broad with no well-defined $k_F$, will further enhance the upper boundary of the particle-hole continuum, damping even the mode with repulsive interactions.

An important future direction for research is to explore how these results change when an explicit time dependence of $J^z$ is introduced. In particular it is important to understand how slowly $J^z$ has to be turned on in order to recover the results of this paper.
