Sonographic Nomogram of the Leptomeninges (Pia-Glial Plate) and Its Usefulness for Evaluating Bacterial Meningitis in Infants

Sigrid Jéquier and Jean-Claude Jéquier

BACKGROUND AND PURPOSE: To our knowledge, the upper limits of the thickness of normal meninges on neurosonograms are not known. We therefore established a nomogram for sonographic measurements of the leptomeninges (pia-glial plate) and assessed its usefulness in neurosonographic examinations of children with bacterial meningitis.

METHODS: The pia mater–cortical glia limitans complex on the surface of the brain and in the sulcus of a frontal gyrus was measured on neurosonograms in 100 infants without meningeal disease in order to establish a nomogram of the thickness of this pia-glial plate, referred to as the leptomeninx. Effects of prematurity, age, sex, and single-layer (surface) versus double-layer (sulcus) measurements were analyzed. Meningeal thicknesses derived from a retrospective analysis of the neurosonograms of 33 patients with purulent meningitis and a prospective study of 22 patients with bacterial meningitis were compared with the nomograms. Clinical outcomes of children with meningeal thickening were compared with those of affected children with normal meninges.

RESULTS: The distribution of sulci measurements was significantly asymmetrical around the mean. Statistical data showed no influence of prematurity and sex, but showed surface measurements to be more consistent than sulcal measurements. Older chronological age was related to slightly larger sulci, but did not influence the surface measurements. In children with bacterial meningitis, the surface meninges were less frequently thickened than were the sulci. Sulcal enlargement occurred often in combination with echogenic deposits in the subarachnoid space.

CONCLUSION: Leptomeninges are best measured on the surface of a gyrus rather than in a sulcus, as the normal thickness of the sulci shows much more variability. Clinical outcome of bacterial meningitis cannot be predicted by presence or absence of meningeal thickening as the only sonographic abnormality.
Fig 1. Coronal neurosonogram of a newborn term baby with duodenal atresia. The echogenic surface of a frontal gyrus (arrow) and the width of a sulcus (arrowhead) are measured.

Methods

One hundred infants aged 1 day to 64 weeks (median age, 8.5 weeks) without meningeal disease or intracranial hemorrhage exceeding grade 1 had transfontanellar sonography requested for various reasons, such as prematurity, apnea, convulsions, asphyxia, macrocrania, or to search for malformations in association with intestinal atresia or for malformative syndromes. Seventy-three were term infants; 55 were male and 45 were female. Premature infants of less than 28 weeks’ gestation do not have sufficient gyral formation and therefore no sulci, and were excluded from the study. No sign of brain abnormality was seen in any of the infants on clinical follow-up examinations during hospitalization or upon their return to the hospital after discharge during the following year.

The neurosonograms were done with an Acuson sonographic machine (Mountain View, CA) with a 7- or 5-MHz sector scan head, depending on the size of the brain. In all infants, a 7-MHz linear transducer was used for examinations of the brain surface. The leptomeninges were measured on screen by electronic calipers on the surface of a frontal gyrus as a single layer and as a double layer inside a frontal sulcus.

Fig 2. Coronal neurosonogram of a healthy 4-week-old baby shows a frontal sulcus of 2 mm on the left (arrows); however, on the right, a faulty measurement of 5.6 mm (asterisk) would have been obtained if the measurement criteria described in the text were not respected.

The leptomeninges were considered to be thickened when a virtual (subdural) space, is usually not distinguishable as an individual structure and cannot be separated from the echo signal arising from scalp, calvaria, dura mater, and arachnoid combined, unless there is a subdural effusion. The echogenicity of the brain surface thus reflects the echoes of the pia mater and the underlying glia limitans membrane of the cerebral cortex, to which it is closely attached. This pia-glial plate was measured on the surface of a frontal gyrus as a single layer and as a double layer inside a frontal sulcus.

Issues such as the best place to measure the leptomeninges and the influence of age, sex, and prematurity were addressed by statistical analysis.

The variables of age, sex, prematurity, and single and double measurements were recorded. Statistical analyses (Statistica, Statsoft, Tulsa, OK) were performed to determine the characteristics of distribution (eg, mean, SD, minimum, maximum, median, skew, and standard error of the skew of each measurement). The expected normal distribution around the mean was fitted on the histogram of the observed frequencies. Kolmogorov-Smirnov and Lilliefors tests were performed to assess the goodness-of-fit of a normal distribution with the histogram.

The effect of sex and prematurity was determined by analyses of variance (ANOVA) to assess the influence of these factors taken separately or as a function of their interaction. The regression of age in weeks with each measurement was computed for gestational age, chronological age, and the sum of both. The relationship between the two measurements was illustrated graphically as a scattergram with a polynomial regression of the third degree with its 95% confidence interval and also with an ellipse of the 95% confidence interval around the common means.

Clinical charts and the transfontanellar sonograms of 50 consecutive patients less than 1 year old with bacterial meningitis and neurosonograms obtained between 1988 and 1995 were reviewed retrospectively (group A). These patients represent about 75% of babies with purulent meningitis; in the other 25%, no neurosonogram had been requested by the clinician. Whenever feasible, the thickness of the meninges of the surface of a frontal gyrus and within a frontal sulcus was measured by hand with mechanical calipers. In 41 infants, the examinations had been done with a Diasonics (Milpitas, CA) sonographic machine using only a 7.5-MHz neonatal head transducer. The remaining nine patients were imaged with an Acuson machine and a 7- or 5-MHz sector scan, and seven of these nine had also been examined with a linear 7-MHz probe. After the nomogram was established, the meninges of 22 children with proved bacterial meningitis in whom sonograms had been obtained (group B) were measured prospectively at the same sites as in group A. In these patients, sonography had been performed using an Acuson machine with a 7- or 5-MHz sector probe as well as a 7-MHz linear probe. All measurements were done on the linear probe neurosonogram with electronic calipers. The clinical selection of the patients was similar in both groups.

The leptomeninges were considered to be thickened when a single layer was thicker than 1.3 mm and/or a sulcus was thicker than 2 mm. In both groups, the subarachnoid space was

measured as the nearest distance between the brain surface and the ipsilateral wall of the sagittal sinus and was considered enlarged if it exceeded 3.2 mm (6). The echogenicity of the fluid in the subarachnoid space was considered normal when it was anechoic except for crossing vessels and abnormal when it contained echogenic particles or deposits. The final clinical outcome was compared with the results of the initial and, sometimes, follow-up sonographic examinations to assess the prognostic significance of meningeal thickening.

Results

Table 1 shows the distribution characteristics of the measurements of the normal leptomeninges used for the nomogram. Surface meninges (single measurements) had a thickness (mean ± SD) of 0.71 ± 0.19 mm; range, 0.3 to 1.3 mm; median (50th percentile), 0.70 mm. The thickness of the sulci (double measurements) was 1.26 ± 0.30 mm; range, 0.6 to 2 mm; median, 1.20 mm. The mean, median, SD, and 95% confidence intervals of the mean of the double measurements (sulci) were almost twice those of the single measurements (surface). The skew characteristic provides the degree of asymmetry of the distribution (which is 0 for a normal distribution). The symmetry of distribution for the single measurements and the distribution of the double measurements were significantly skewed to the right (higher values); therefore, high readings in healthy infants could have been misinterpreted as pathologic findings. Lilliefors test, comparing the observed distribution (the histograms) with the statistically normal distribution around the mean, was significant, confirming the fact that the distribution of the measurements was not normal around the mean for single and double measurements.

To illustrate these findings, the histograms of single (Fig 3A) and double (Fig 3B) measurements are shown. The distribution of single measurements and the observed double measurements do not fit the expected values of a normal distribution. Indeed, lower readings are too high, and higher readings are also too high. The Kolmogorov-Smirnov test was significant: D = .15094 for single measurements, and D = .15830, P < .05 for the single and double measurements, respectively. Lilliefors test was also significant (P < .01) for both measurements. These results illustrate the significant lack-of-fit of the expected normal distribution of the observed frequencies of each of the histograms. As shown in the scatter plot (Fig 4), an ellipse of 95% confidence limits around both means illustrates the relation between the two measurements. A number of double measurements greater than the expected 95% will

Fig 3. A and B, Histograms of observed distribution of the readings of single measurements (surface, A) and double measurements (sulci, B) with the expected normal distribution computed with the SD around the mean. The normal, symmetrical, expected distribution does not satisfactorily fit the observed data of the single and double measurements. Kolmogorov-Smirnov test: D = 0.15094 for single measurements, and D = 0.15830 for double measurements; P < .05 for both measurements. Lilliefors test: P < .01 for both measurements. All tests were significant, demonstrating an insufficient goodness-of-fit of the expected normal distribution with the observed frequencies.

Fig 4. Scatterplot of single and double measurements, with third-degree polynomial regression and its 95% confidence limits and an ellipse of the 95% confidence limits around the common mean of both measurements. A number of readings are outside the 95% confidence limits. A number of readings are outside the 95% confidence limits. The scales of the measurements differ for graphic reasons. The correlation coefficient is statistically significant (r = .435, P < .001). Most outliers are located at the higher end of the measurements.
not fit into the ellipse, owing to outliers, especially for higher values. This ellipse is another way to illustrate the combination of two normal distributions. Even if the correlation between the single and double measurements was significant \( r = 0.435, P < .001 \), a great deal of dispersion is present around the polynomial regression line, owing to scattered sulci readings.

The significant lack-of-fit of the normal model, especially on the side of higher readings, which should represent the critical boundaries between normal and abnormal findings, requires the use of a nonparametric description of the data. The histograms of cumulated frequencies are shown in Figure 5, with the same scale for both measurements. Because 100 subjects were used, this represents the equivalent of a percentile distribution. The 95th percentile is graphically equal to 1.0 mm and 1.8 mm for the single and double measurements, respectively. Smoothing of the histograms can be done by hand by connecting the middle of the successive columns. Any value of decile, quartile, or median can be recovered directly on the chart, without any assumption of a mathematical underlying function, except for continuity.

Some additional analyses were also performed for completeness. The ANOVA test (results not reported), performed separately on the single and double measurements, showed no significant effect of sex or prematurity. There was no significant regression of single-surface measurements with gestational age, chronological age, or the sum of both (measured in weeks). There was, however, a significant positive correlation between sulci measurements and chronological age \( r = 0.357, P < .003 \) and between sulci measurements and the sum of gestational age and chronological age \( r = 0.396, P < .001 \), but not between sulci measurements and gestational age alone.

An ancillary finding on the histograms was the unequal frequency of reporting for the different thickness readings in tenths of a millimeter. This suggests that the resolution of the measurements was closer to 0.2 mm than to 0.1 mm, although the reported axial resolution of the machines is 0.3 mm. This finding should not affect the distribution measurements.

The results of the neurosonograms of children with bacterial meningitis are summarized in Table 2. To reiterate, in group A, meningeal thickness was analyzed retrospectively and in group B, the analysis was prospective. Surface meninges were not measurable in nine (18%) of 50 patients in group A and in four (18%) of 22 patients in group B; the reasons included a faulty technique and a lack of examination with a linear scan head in two patients in group A, and compressed subarachnoid space and brain edema or dilated ventricles in the others. Sulci could not be measured in two (4%) of 50 children in group A and in four (18%) of 22 patients in group B, because of brain edema or hydrocephalus. The subarachnoid space was obliterated in 10 patients in group A and in three patients in group B, preventing measurement and assessment of the echogenicity of the fluid.

Increased surface meningeal thickness was found in 15 (37%) of 41 children in group A and in five (28%) of 18 children in group B; all these patients also had enlarged sulci. Sulci were found to be thickened in 28 (58%) of 48 children in group A and in eight (44%) of 18 children in group B. Echogenic subarachnoid fluid was seen in 13 (33%) of 40 patients in group A and in eight (42%) of 19 in group B (Fig 6), and was seen in combination with...
mediate layer becomes the arachnoid (7). Neither

These cells separate into three layers: the outer lay-

ers form the dura mater (and calvaria), the inter-

mediate layer becomes the arachnoid (7). Neither

of these can normally be identified by sonography,
as they cannot be separated from the bony calvaria
or the skull base. The inner pia mater, however,
separated from the arachnoid by the fluid-filled
subarachnoid space, is easily seen on sonograms in
most patients with an open anterior fontanel. It
closely follows the cortex of the brain and invests
the sulci. Histologically, it contains collagenous fi-
bers on the outside and elastic fibers on the inside,
adhers to the neural tissue to form the pia-glial
plate, and contains bridging vessels.

Meningeal thickening is nonspecific and may be
due to an increase in any of the normal constitu-
ents, such as collagen deposition; fibromatosis (8);
infiltration by inflammatory cells (eg, infection)
(9), rheumatoid disease (10), sarcoidosis (11); vas-
culitis (12); infiltration by benign or malignant neo-
plastic cells, (eg, gliomatosis) (13), lymphoma (14),
carcinoma (8), or melanosis (15); deposition of ab-
normal metabolic products (eg, Gaucher disease, amyloidosis) (16), hemosiderin deposit (17); or
dysplastic angiomatosis (18) (Sturge Weber dis-
ease). Reactive collagen deposition can occur after
surgery (19) (eg, after shunting of hydrocephalus).
Reactive meningeal thickening is also seen after in-
trathecal chemotherapy (20). Many of these dis-
eases may not cause macroscopic meningeal thick-
ening; and although it seems useful to have
reproducible criteria for the upper limits of normal
meningeal thickness, normal values do not indicate
absence of disease.

Sonography reveals not only the pia mater but
also the underlying glia limitans. Many pathologic
entities affect the superficial and penetrating ves-
sels, the perivascular space, the blood-brain barrier,
and therefore the pia-glial complex, which is seen
as a unique echogenic structure. In establishing a
nomogram for normal thickness of the leptomene-
ings by sonography, statistical computation is jus-
tified to determine the validity of the measure-
ments, especially the boundary between health and
disease, if the readings are to be interpreted by in-
ference from a model of suitable distribution. The
characteristics of distribution are of importance in
determining whether the distribution is statistically
normal. If normality is proved, mean, SD, and
parametric comparison tests can be used (ie, t-test,
ANOVA). If normality is not confirmed, nonpara-
metric procedures must be used; for example, de-
scription in percentiles and nonparametric compar-
ison tests (ie, Wilcoxon, Mann-Whitney).

The results of the various computations carried
out to determine the characteristics of the distri-
bution establish the usefulness of single measure-
ments in determining acceptable upper limits in
healthy infants. The same computations with dou-
ble measurements provide evidence that great care
should be exercised in the interpretation of high
readings. Readings of both measurements will not
add precision to the assessment of the clinical sta-
tus of an infant, as shown by the great number of
outliers off the 95% limits of the ellipse around the

Discussion

The meninges originate from mesenchymal cells
surrounding the early embryonic telencephalon.
These cells separate into three layers: the outer lay-
er forms the dura mater (and calvaria), the inter-
mediate layer becomes the arachnoid (7). Neither

sulcal enlargement in all but one patient with asept-
ic meningitis who had been treated with antibiotics
before admission to the hospital. Ventricular en-
largement was seen in 13 patients in group A and
in two patients in group B. Only three needed

Fig 6. Coronal sonogram of a 3½-week-old infant with pneu-
mococcal meningitis. The surface meninges are of normal thick-
ness (0.8 mm). The subarachnoid space, the interhemispheric
fissure, and the sulci are filled with echogenic material (pus and
proteins by lumbar puncture). The frontal sulcus is enlarged (2.4
mm) and its undersurface is poorly defined.
common means (Fig 4). The safe way to assess the meaning of a measurement is to use a percentile distribution, which does not imply any mathematical function except continuity. A much greater number of cases could justify the smoothing of individual columns.

The axial resolution of the linear transducer used in this study was 0.3 mm for the Acuson machine. These dimensions are close to those we wanted to measure. Use of higher frequency transducers may improve the accuracy of our data.

In children, meningitis is by far the most common cause of leptomeningeal thickening, followed by posthemorrhagic or postsurgical reaction. Transfontanellar sonography is often requested in newborns and infants with meningitis to look for such complications as hydrocephalus, abscess, ventriculitis, encephalitis, and so on. Meningeal thickening has been reported in many infants with purulent meningitis, but the prognostic value of such a sonographic finding has not been established.

In our series of patients with bacterial meningitis (groups A and B), meningeal thickening occurred in the sulci in 44% to 56% and in the surface leptomeninges in only 28% to 39%; 35% had echogenic subarachnoid fluid. All patients with echogenic subarachnoid fluid also had sulcal enlargement. We presume that increased meningeal thickness may be due to deposits of pus and fibrin as well as to actual infiltration by inflammatory cells. All patients in whom de novo neurologic sequelae developed had meningeal thickening at sonography, except for the one in whom the meninges could not be measured because of brain edema. However, over 75% of patients with similar sonographic findings of the meninges recovered clinically. Brain edema and compression of the meninges to a point where they could not be measured was related to an unfavorable outcome.

**Conclusion**

Meninges are considered to be abnormally thick when neurosonographic measurements exceed 1.3 mm on the surface of a gyrus or 2 mm within a sulcus. Absence of meningeal thickening does not exclude a diagnosis of meningitis, as brain edema may prevent visible meningeal thickening, and fatal toxic shock may occur very rapidly, leaving no time for the meninges to react in a visible way. Although the majority of the children with neurologic sequelae after meningitis also had meningeal thickening during the active phase of the disease, most of the children with bacterial meningitis and meningeal thickening did well. No clinical prognosis should be established on the basis of meningeal thickening as the only abnormal sonographic finding.
