Quantum light: The puzzling predictions of entanglement are coming of age

GISIN, Nicolas, TANZILLI, Sébastien, TITTEL, Wolfgang

Abstract

Entanglement is the physical property that marks the most striking deviation of the quantum from the classical world. It has been mentioned first by the great Austrian Physicist Erwin Schrödinger in 1935 (an introduction to this and other quantum phenomena is given in [1]). Yet, despite this theoretical prediction now being 80 years old, and the famous experimental verifications by Alain Aspect dating back to the early eighties [2], entanglement and its use entered mainstream physics as a key element of quantum information science [3] only in the 1990’s.

Entanglement is the physical property that marks the most striking deviation of the quantum from the classical world. It has been mentioned first by the great Austrian Physicist Erwin Schrödinger in 1935 (an introduction to this and other quantum phenomena is given in [1]). Yet, despite this theoretical prediction now being 80 years old, and the famous experimental verifications by Alain Aspect dating back to the early eighties [2], entanglement and its use entered mainstream physics as a key element of quantum information science [3] only in the 1990’s.
The academic research into entanglement nicely illustrates the interplay between fundamental science and applications, as well as the need to foster both aspects to advance either one. For instance, the possibility to distribute entangled photons over tens or even hundreds of kilometers is fascinating because it confirms the quantum predictions over large distances, while quantum theory is often presented to apply to the very small (see Figure 1). On the other hand, entanglement enables quantum key distribution (QKD) [1]. This most advanced application of quantum information processing allows one to distribute cryptographic keys in a provably secure manner. For this, one merely has to measure the two halves of an entangled pair of photons. Surprisingly, and being of both fundamental and practical interest, the use of entanglement removes even the necessity for trusting most equipment used for the measurements [5]. Furthermore, entanglement serves as a resource for quantum teleportation (see Figure 2) [1]. In turn, this provides a tool for extending quantum key distribution to arbitrarily large distances and building large-scale networks that connect future quantum computers and atomic clocks [6].

In the following, we describe the counter-intuitive properties of entangled particles as well as a few recent experiments that address fundamental and applied aspects of quantum teleportation. While a lot of work is being done using different quantum systems, including trapped ions, colour centres in diamond, quantum dots, and superconducting circuits, we will restrict ourselves to experiments involving photons due to their suitability to experiments involving photons due to their suitability for building future quantum networks.

**Entanglement – a puzzling consequence of quantum theory**

Entanglement manifests itself through highly, if not perfectly, correlated results of measurements performed on particles that can in principle be arbitrarily far away – say, one on the earth, and one on the moon. If we consider two photons and their polarization as an example, quantum theory describes, and experiments confirm, that photon 1 might be found horizontally polarized, and photon 2 vertically polarized. Or vice versa. What is more, one might also find that one photon is polarized at 45° and the other one at -45°. All what is known in advance is that the two photons are orthogonally polarized.

What is particularly discomforting about these correlations is that they cannot be explained by attributing properties to the individual photons that determine, irrespective of what happens to the other photon, how each will respond to its measurement. Entangled particles behave in unison, regardless of their separation and even if they are measured simultaneously. The result of a quantum measurement is random, but, somehow, this

![Quantum teleportation diagram](image-url)
for the case of a quantum object, the quantum no-cloning theorem [1] tells us that perfect copying of, say, the photon’s polarization is impossible.

Quantum teleportation, proposed in 1993 and first experimentally demonstrated at the Universities of Rome and Innsbruck in 1997, allows the flawless transfer of a property between two quantum particles – e.g., two photons – without running into a contradiction with the no-cloning theorem (see [8] for a recent review article). As explained in Fig. 2a, it requires three particles – one whose property is to be teleported (A), and two that are originally entangled (C and B). The comparative measurement of the property of the first photon with that of one member of the entangled pair allows transferring it from the first photon onto the second member of the pair. This measurement – the so-called Bell-state measurement – is named after the Northern Irish Physicist John Bell, who has played a seminal role in establishing the science of entanglement. The first photon loses its property during this measurement, that is, there is no ‘copying’ during teleportation. Moreover, the transfer does not happen instantaneously (something that is often claimed erroneously in the non-scientific literature), and hence there is no contradiction with another pillar of modern physics either – that of special relativity.

An application of quantum teleportation - extending the reach

Only five years after its discovery, it was realized that quantum teleportation is not only an intriguing manifestation of the puzzling predictions of quantum theory. Together with the possibility to transfer properties from flying photons onto stationary particles (i.e., to create quantum memory for light), it allows establishing entanglement over theoretically arbitrarily long distances by means of quantum repeaters [8]. This would allow building ultra-long-distance QKD links as well as quantum networks across countries, continents, or even the globe.

The first step in this direction was demonstrated in 2003 at the University of Geneva, when the photon that received the teleported property (photon B in Figure 2a) was sent over 2 km of spooled, standard telecommunication fiber before being measured [9]. This demonstration was extended in 2007 to more than 800 m of deployed fiber that was part of the Swisscom fiber network [10] (see Figure 3a). In this experiment the receiving photon was already hundreds of meters away when the qubit to be teleported was prepared. More recently, the transmission distance of photon B was extended to more than 100 km of air by researchers at the University of Vienna as well as the University of Science and Technology in Hefei [8].

The next step is to extend the distance over which the other two photons (photon A and C in Fig. 2a) travel.
before meeting for the Bell-state measurement. However, due to the difficulty of avoiding any modification of either photon during transmission, this challenge has not yet been met outside a well-controlled laboratory. An important step in this direction has been the recent demonstration by researchers at the University of Calgary of a Bell-state measurement – not a full quantum teleportation experiment – with photons that have been created at different places within the city of Calgary and travelled through the standard telecommunication fiber network before being measured [11] (see Figure 3b).

Another key achievement on the path towards a quantum network has been last year’s teleportation at the University of Geneva of a property from a photon into a rare-earth-ion doped crystal, which stored it for 50 nanoseconds [12]. Notably, both photons that took part in the Bell-state measurement travelled over 12.5 km of spooled fiber, thereby also meeting the above-described requirement for building extended quantum networks. This demonstration built on the previous observation that such crystals are suitable for storing members from entangled photon pairs, which was reported in 2011 by researchers in Geneva as well as in Calgary [13].

**A fundamental question – teleportation of multiple properties**

With very few exceptions, all quantum teleportation experiments to date demonstrated the transfer of a single property of one particle, e.g., the polarization of a photon. However, objects encountered in our every-day life are composed of many elementary building blocks, e.g., many atoms, each of which being described by several properties. A natural question is therefore if one can teleport more complex quantum systems as well. Indeed, this is possible. A first guess may lead to the idea of teleporting all properties individually in a straightforward generalization of the scheme shown in Figure 2a. This guess is correct – most surprisingly even if the properties are entangled!

However, in the case of teleporting several properties encoded into the same particle, there is an interesting twist – at least in the scheme employed by researchers from the University of Science and Technology in Heifei in 2015 to transfer the angular orbital momentum and the polarization of a single photon [14]. As shown in Figure 2b, it requires, as an intermediate step, the confirmation that exactly one photon traveled along each of the two paths connecting the measurement that teleports the first property (the orbital angular momentum) with the measurement that teleports the second one (the polarization). Obviously, the use of standard single photon detectors is not a viable solution, as the photons would be destroyed during the measurements. But interestingly a standard “single property teleporter” does the job. Indeed, a successful Bell-state measurement does not only transfer a property from one photon onto another photon (a process that is not distinguishable from the direct transmission of the original photon through the teleporter), but also confirms that the photon existed! This idea generalizes from two to any number of properties: an n-property teleporter requires an (n-1)-property teleporter as a plug-in, which itself requires an (n-2)-property teleporter, etc.

Figure 4 shows a fully integrated “on-chip” realization of a one-property teleporter, developed at the University of Nice [15], that would constitute a good starting point for building such a nested scheme.

As one can see from these insights into current research, many fundamental problems related to entanglement and teleportation remain to be solved. Furthermore, on the application side, the connection of distant nodes into quantum networks, which will enable provably secure communication and networked quantum computers, will remain an important challenge for many years to come. One thing is clear: this highly multi-disciplinary field will continue to be exciting!

**About the Authors**

 Nicolas Gisin is a Professor and Director of the Department of Applied Physics at the University of Geneva. His activities range from foundations of quantum physics to applications in quantum communications.

 Sébastien Tanzilli is a CNRS Research Director at the University Nice Sophia Antipolis. He aims at exploiting integrated photonics as an enabling technology for quantum communication and fundamental quantum optics.
Wolfgang Tittel is a Professor and Chair for Quantum Secured Communication at the University of Calgary in Canada. He aims at exploiting entanglement as well as rare-earth doped crystals and fibers to establish long-distance quantum communication links.

[Letter to the Editor]

by Frank Israel, Sterrewacht Leiden

Dear Editor,

The article: "Light, cosmic messages from the past" in EPN 46-4 contained two small errors.

- Sanduleak was not a star but a person. Nicholas Sanduleak was an American astronomer of Rumanian origin who published in 1970 a catalogue of stars in the Large Magellanic Cloud. The precursor of SN 1987A was listed in this catalogue and is referred to as Sk -69° 202a (or Sanduleak -69° 202a).
- The supernova remnant Cas A was observed for the first time in the 20th century, not in 1680. The supernova explosion that created the remnant occurred at some time in the 17th century, but there are no unequivocal records of its occurrence. The very bright star was probably obscured by dense clouds of dust in the line of sight.

The author responds

We agree with the comment that the blue supergiant star, progenitor to supernova 1987A in the Large Magellanic Cloud was officially named Sanduleak -69° 202. We apologize for the sloppiness.

To the second comment, we agree that the remnant of Cas A is officially first observed in the 20th century as a radio source. Optical and x-ray observation identified that source to be an expanding supernova remnant of a supernova that has exploded about 340 years ago (from today). There have been frequent discussions and arguments ever since if that remnant is associated with a suddenly appearing and short-lived bright star that was observed in 1680 by the British Astronomer Royal John Flamsteed at (or near) that location. (David W. Hughes: Did Flamsteed see the Cassiopeia A supernova?, *Nature* 285, 132-133 (1980). That possible observation is what we have been referring to.
