ABSTRACT

Fibrinogen is an abundant protein synthesized in the liver, present in human blood plasma at concentrations ranging from 1.5-4 g/L in healthy individuals with a normal half-life of 3-5 days. With fibrin, produced by thrombin-mediated cleavage, fibrinogen plays important roles in many physiological processes. Indeed, the formation of a stable blood clot, containing polymerized and cross-linked fibrin, is crucial to prevent blood loss and drive wound healing upon vascular injury. A balance between clotting, notably the conversion of fibrinogen to fibrin, and fibrinolysis, the proteolytic degradation of the fibrin mesh, is essential. Disruption of this equilibrium can cause disease in distinct manners. While some pathological conditions are the consequence of altered levels of fibrinogen, others are related to structural properties of the molecule. The source of fibrinogen expression and the localization of fibrinogen protein also have clinical implications. Low levels of fibrinogen expression have been detected in extra-hepatic tissues, including carcinomas, potentially contributing to disease. Fibrinogen deposits at aberrant sites including the central nervous system or kidney, can also be pathological. In this review, we discuss disorders in which fibrinogen and fibrin are implicated, highlighting mechanisms that may contribute to disease.

Introduction

Fibrinogen biosynthesis takes place in hepatocytes, starting with expression of three genes, FGA, FGB and FGG, clustered in a 50 kb region of human chromosome 4. The genes encode fibrinogen Aα, Bβ and γ chains, respectively. Both FGA and FGG are transcribed to produce two transcripts. The major transcript encoding Aα is transcribed from five exons, but a minor transcript, resulting from splicing of a sixth exon, encodes the AαE chain which is present in 1-3% of circulating fibrinogen molecules. For FGG, a major γ chain mRNA is transcribed from ten exons while in the minor γ chain intron 9 is retained, substituting the four amino acids encoded by exon 10 with 20 γ COOH-terminal residues. γγ′ γ′/γ′ represent approximately 8 to 15% of a healthy person’s total fibrinogen.

The fibrinogen genes are co-regulated both for basal expression and when upregulated upon an inflammation-driven acute phase response. The latter leads to a prompt increase in plasma fibrinogen after bleeding or clotting events, or to support wound healing. Each fibrinogen gene is thought to be regulated by a proximal promoter and local enhancer elements. These appear to act together with tissue-restricted transcription factors, regulatory chromatin marks and a looped architecture to co-regulate expression of the three-gene cluster. CpG DNA methylation of the fibrinogen regulatory regions, and microRNA can also contribute to cell- and state-specific fibrinogen expression.

Fibrinogen mRNA is translated into nascent polypeptides with signal peptides that are cleaved in the lumen of the endoplasmic reticulum. Here the chains assemble, with the assistance of chaperones, first as Aαγ or Bβγ dimers and then as trimERIC molecules, by addition of the missing chain. NH-terminal disulfide bridges connect two trimers producing hexameric molecules. These transit to the Golgi apparatus, where the final Bβ and γ chain N-glycosylation steps take place.
properly assembled fibrinogen is secreted as a 340 kDa glycoprotein, misfolded proteins are retained intracellularly and degraded by quality control mechanisms.10

During human development, hemostatic proteins, including fibrinogen, are present in plasma around the time of the termination of hepatic histogenesis and spleen vascularization (~10–11 weeks of gestation), reaching levels at term similar to those in the adult.11 Fetal fibrinogen has qualitative differences, notably delayed fibrin formation, which persist for approximately 1 year after birth. Neonatal clots are less dense than those of an adult and have a different three-dimensional structure.12 However, this does not have a significant impact on coagulation parameters such as bleeding time.

Circulating fibrinogen promotes hemostasis as the soluble fibrin precursor, but also by bridging activated platelets, and enabling a correct disposition of erythrocytes, macrophages and fibroblasts around a wound.13 The development and control of these processes is important to stop bleeding, enhance wound healing and promote tissue regeneration. In addition, fibrinogen is implicated in preventing microbial invasion and proliferation upon trauma,14 enhancing host defenses through the assembly of matrices that entrap invaders and recruit and activate host immune cells.15

The association of fibrinogen with disease results from different mechanisms. These include triggering signaling pathways within given physiological contexts, and alterations in the normal range of fibrinogen levels or in its structure. The latter can contribute to altered fibrin clot properties which can impair thrombin and plasminogen binding. In this review, we focus on the involvement of fibrinogen in the development of a range of human disorders, describing its role in different pathological mechanisms.

**Bleeding disorders**

Bleeding or hemorrhage is the escape of blood from the closed cardiovascular system due to damaged blood vessels.16 The natural control of bleeding is known as hemostasis.17 Many defects in hemostatic proteins, including fibrinogen, can cause pathological hemorrhage.

Quantitative and qualitative variations in fibrinogen plasma levels can be inherited or acquired. Inherited disorders are divided into type I and II.18 Type I, comprising afibrinogenemia and hypofibrinogenemia, affect the concentration of plasma fibrinogen (<1.5 g/L). Type II, including dysfibrinogenemia and hypodysfibrinogenemia, affect the quality of circulating fibrinogen, the latter also affecting plasma levels.19

Afibrinogenemia, which has an estimated prevalence of one to two cases per 10^7 people,20 is an inherited disease characterized by the absence of circulating fibrinogen due to homozygous or compound heterozygous mutations in one of the fibrinogen genes. These may affect mRNA production, splicing or stability, protein production or stability, or hexamer assembly, storage, or secretion.21 An initial case of afibrinogenemia in a 9-year-old boy was described in 1920,22 but the first causative mutation was identified many years later.23 Since then, dozens of other causative mutations have been reported for afibrinogenemia. The majority of these are null mutations, i.e., large deletions, frameshift, early-truncating nonsense, or splice-site mutations. Missense mutations are mostly grouped in the conserved COOH-terminal globular domains of the Bβ and γ chains which has given insights into structural determinants of fibrinogen hexamer assembly and secretion.10

Bleeding is the main symptom of afibrinogenemia, often occurring in the neonatal period at the umbilical cord. The natural course of afibrinogenemia is usually characterized by spontaneous and severe bleeding, involving all tissues, such as the skin, the oral cavity, the genitourinary tract, the gastrointestinal tract and the central nervous system (CNS). Intracranial hemorrhage is potentially fatal.21 In addition, bone kysts, prolonged wound healing and spontaneous spleen rupture are typically observed through the life of afibrinogenemic patients.19 Hemarthroses are also frequent but less invalidating than in patients with hemophilia. Women are particularly at risk of bleeding during the child-bearing period. Even in women with no known fibrinogen disorder, in a prospective study aimed at determining hemostatic markers predictive of the severity of postpartum hemorrhage, only fibrinogen concentration was independently associated after multivariate analysis.26 In particular, a fibrinogen concentration lower than 2 g/L was found to have positive predictive value for bleeding events.

Paradoxically, afibrinogenemic patients are at risk of thrombosis, a finding replicated in fibrinogen-deficient mice, since primary hemostasis enables thrombus formation, but clots lacking fibrin are unstable and tend to embolize.27 The reasons for increased thrombotic risk are not entirely understood, but could be related to the absence of thrombin sequestration by the fibrin clot, leading to excessive platelet activation.28

Fibrinogen infusions are efficient to treat acute bleeding and prevent bleeding in the case of surgery. Plasma-derived fibrinogen concentrate is the treatment of choice, providing the safest and most efficient profile among the sources of fibrinogen. Modalities of long-term fibrinogen supplementation (on-demand versus prophylactic), as well as the optimal trough fibrinogen level to target, are still unresolved issues. Some concerns have been raised regarding a potential link between fibrinogen infusion and the occurrence of thrombotic events, although available clinical and biological data are controversial.37

While the role of fibrinogen in hereditary bleeding disorders is well-documented,30,31 similar afibrinogenemia phenotypes have been reported in mice and zebrafish models. The Fga knock-out mouse (Fga^-/-) shows spontaneous bleeding, loss of platelet agglutination and clotting function and reduced survival. Serious injuries, overcome by wildtype mice, were lethal for the Fga^-/- animals. Females could not maintain gestation and fatal uterine bleeding was observed. Many of the latter effects were corrected by a transgene for the Aα chain, or the AαE isoform, in Fga^-/- mice.32 Fibrinogen-deficient zebras have an adult bleeding phenotype with cephalic and ventral hemorrhaging and reduced survival compared with that of control fish.33 In addition, venous thrombosis could not be induced by laser in embryonic zebrafish, clearly demonstrating a hemostatic deficiency.33

Congenital hypofibrinogenemia is much more frequent than afibrinogenemia and is often caused by heterozygous fibrinogen gene mutations. Recently, a systematic analysis of exome/genome data from about 140,000 individuals belonging to the genome Aggregation Database showed that the worldwide prevalence of recessive fibrinogen dis-
orders varies from 1 in 10⁶ persons in East Asians to 24.5 in 10⁶ persons in non-Finnish Europeans. Subjects with moderate or mild hypofibrinogenaemia are usually asymptomatic since their fibrinogen levels are sufficient to prevent bleeding and pregnancy failure. However, in the presence of another hemostatic abnormality or trauma, they may also bleed and suffer pregnancy loss or postpartum hemorrhage. In some cases, due to mutations in FGG, the mutant fibrinogen forms aggregates in the endoplasmic reticulum of hepatocytes and can cause liver disease.

Qualitative fibrinogen disorders are commonly associated with heterozygous missense mutations in one of the fibrinogen genes and are more frequent than severe quantitative disorders. Although the exact prevalence is not established, it is estimated to be 1 in 100 to 1,000 individuals (0.1-1.0%). Two mutation “hotspots” account for over 70% of the detected dysfibrinogenaemia mutations. They are at the Arg35 codon in exon 2 of FGA, encoding a critical residue in the thrombin cleavage site of the α chain, and the Arg301 codon in exon 8 of FGG, encoding part of the γ chain “hole A” fibrin polymerization site. Other causative missense mutations are mainly located in the COOH-terminus of the α chain which, unlike the β and γ chains, does not contain a large, highly conserved globular domain. Thus, missense mutations in this region do not have a severe impact on hexamer assembly and secretion but can produce a dysfunctional fibrinogen molecule present in the patient’s circulation. Of note, almost all dysfibrinogenaemic variants affect fibrin polymerization, which results in a variable tendency for bleeding. An updated list of dysfibrinogenaemia variants and related phenotypes is available in a recent review and an open-access online database (http://site.geht.org/base-fibrinogene/).

Patients with dysfibrinogenaemia are frequently asymptomatic but can suffer from bleeding and/or thromboembolic complications. Women are particularly at risk of adverse clinical outcomes, including miscarriages or postpartum thromboses. Symptoms are heterogeneous with a poor segregation of the clinical phenotype even among carrier relatives of the same causative mutation. Using integrative hemostatic models, taking into account the molecular anomaly; fibrin clot properties and family history, may improve assessment of a patient’s phenotype.

Acquired fibrinogen diseases are far more common than inherited ones. Acquired hypofibrinogenaemia may result from different causes including disseminated intravascular coagulation, in which activation and consumption of coagulation factors depletes their plasma availability. Fibrinogen degradation products seen in disseminated intravascular coagulation further impair normal fibrinogen function. Low fibrinogen levels due to disseminated intravascular coagulation are commonly observed in patients with acute promyelocytic leukemia. Patients with liver disease can also have low plasma fibrinogen due to impaired production. Hemodilution, massive hemorrhage or medication affecting liver protein biosynthesis can also contribute to hypofibrinogenaemia. Acquired dysfibrinogenaemia results from a health condition e.g., liver disease affecting post-translational modifications of fibrinogen, notably sialylation. Autoantibodies interfering with the physiological functions of fibrinogen have also been reported. As reviewed previously, several studies have investigated the use of fibrinogen replacement in acquired coagulopathies. Although it is an important treatment option for acquired coagulopathic bleeding, more studies in different clinical settings are necessary to optimize the dosage. In addition, hyperfibrinolysis contributes to the bleeding manifestations in these acquired coagulopathies, highlighting the importance of a subtle balance between fibrin formation and fibrin degradation. Lysine analogues (e.g., tranexamic acid) have proven their efficacy in selected clinical situations, such as major trauma (CRASH-2 trial) and postpartum hemorrhage (WOMAN trial).

Cardiovascular disease

Thrombosis occurs in the major cardiovascular diseases (CVD): ischemic heart disease, stroke, and venous thromboembolism. Arterial thrombosis is associated with the formation and rupture of an atherosclerotic plaque leading to accumulation of platelets, whereas venous thrombosis is linked to endothelial dysfunction and blood stasis which trigger the aggregation of fibrin and red blood cells. The involvement of elevated fibrinogen as a risk factor for CVD remains controversial. Early prospective studies found a clear relationship between plasma fibrinogen and CVD event risk and the most comprehensive analysis to date confirmed this. Data from 154,211 subjects with no known history of coronary heart disease or stroke, from 31 prospective studies, revealed associations between fibrinogen level, major ischemic cardiovascular events and nonvascular mortality. The hazard ratio for coronary heart disease and stroke was 1.8 per g/L increase in plasma fibrinogen. Similar conclusions were drawn from a study on the presence and severity of new-onset coronary atherosclerosis in the Han Chinese population. In 2,288 subjects referred for coronary angiography, plasma fibrinogen was positively associated with the presence and severity of coronary atherosclerosis, after adjustment for cardiovascular risk factors.

Biases in these evaluations may exist due to unmeasured confounding factors and causality between plasma fibrinogen and CVD events cannot be demonstrated. The elevated fibrinogen levels measured may result from an inflammatory state caused by the underlying pathology, and therefore be a consequence of the illness itself. Nevertheless, further evidence reinforces the hypothesis that the fibrinogen level may directly influence CVD events or progression. Intravenous infusion of human fibrinogen into mice, giving a 1.7-fold increase in plasma fibrinogen, led to resistance to thrombolysis, increased thrombus fibrin content, quicker fibrin formation, greater fibrin network density and increased clot strength and stability. The appeal of fibrinogen as a causal factor for CVD comes from its roles in both thrombosis and inflammation. Higher levels of fibrinogen can promote CVD events through different pathways (Figure 1A), which, even if they result from a pre-existing inflammatory condition, may further contribute to a poorer clinical state. Fibrinogen may favor atherogenesis when converted to fibrin and its atherogenic degradation products, or trigger lipid deposition and local inflammation resulting in the formation, destabilization, and rupture of atherosclerotic plaques. Promotion of thrombogenesis is another possible mechanism. Fibrinogen acts as a scaffold for blood clots, enhancing platelet aggregation and fibrin formation, making thrombi more resistant to lysis. Furthermore,
Fibrinogen can interact with red blood cells, mediating erythrocyte sedimentation and blood viscosity, while also permitting red blood cells to attach to thrombi. Besides contributing to thrombus size, structure, and stability, red blood cells can alter fibrin network organization, suppress plasmin generation and reduce clot resolution, possibly delaying fibrinolysis and prolonging clot formation, which may contribute to CVD.

Fibrinogen is also a selective matrix metalloproteinase 2 (MMP-2) inhibitor. High plasma fibrinogen levels could lead to MMP-2 insufficiency in humans. As this enzyme is vital for healthy organ development and repair, excessive MMP-2 inhibition could result in arthritic and cardiac disorders similar to those seen in patients with MMP-2 gene deficiency.

There is, therefore, a potential clinical interest in fibrinogen-lowering drugs for the prevention and/or treatment of CVD. However, some studies have not found a link between high plasma fibrinogen levels and disease. While several single nucleotide polymorphisms have been associated with elevated fibrinogen, the analysis of 24 independent genome-wide significant single nucleotide polymorphisms in 28 European ancestry cohorts, including 91,323 individuals, did not support a causal relationship between plasma fibrinogen and CVD events. A more recent Mendelian randomization study using genetic variants to uncover evidence for a causal relationship between fibrinogen as a modifiable risk factor, and CVD events as an outcome, came to similar conclusions. After accounting for horizontal pleiotropy, the effect of fibrinogen on CVD is likely to be small and so resolving any causal effect will require further analysis using larger sample sizes.

Structural variability in fibrinogen can be linked to CVD. Increased plasma fibrinogen γ' concentration is associated with the risk of myocardial infarction and other thrombotic states. Epidemiological data suggest decreased levels of γ' may be associated with venous thrombosis, due to the capacity of γ' to counteract a common risk factor for venous thrombosis i.e. plasma activated protein C resistance. However, increased levels of fibrinogen γ' are associated with arterial thrombosis. This has been attributed to the capacity of the γ' chain to modulate the fibrin clot architecture toward a more thrombotic fibrin network. Whether γ' is causal in this disease or a consequence of increased inflammation is not clear, and further studies are necessary to evaluate the hemostatic properties of fibrinogen γ' depending on the disease type. Nevertheless, haplotype data are concordant: a haplotype which shows decreased fibrinogen γ' levels was associated with an increased risk of venous but not arterial thrombosis in different studies. By contrast, a haplotype linked to increased γ' was associated with arterial thrombosis, although contradictory results have been reported.

Fibrinogen variants found in congenital dysfibrinogenemia can contribute to CVD in different ways (Figure 1B). These include elevated levels of free thrombin resulting from impaired binding to fibrinogen, or altered strength, structure and stability of the fibrin clot, prompting embolization or compromised fibrinolysis. In particular, patients carrying dysfibrinogenemene mutations which sig-

---

(B) Effects of structural variations in fibrinogen. This figure was prepared using BioRender.com. MMP-2: matrix metalloproteinase 2.
significantly increase thrombosis risk (Online Supplementary Table S1) can have a family history of CVD, and experience thrombotic events at a young age. Interestingly, four out of seven mutations result in an amino acid change to cysteine, which may bind to albumin, resulting in structurally abnormal clots. Polymorphisms in the fibrinogen genes have also been linked to CVD: for example, A α p.Thr331Ala, which alters factor XIII-mediated cross-linking, results in fibrin clots prone to undergo embolization. Post-translational modifications of fibrinogen (e.g., oxidation, phosphorylation, glycosylation and sialylation), might also have a role in CVD by affecting clot architecture, the rate and form of fibrin networks or the interaction with platelets and fibrinolysis. In accordance with this, dysfibrinogenemic variants that result in the over-sialylation of fibrinogen, aberrant fibrin polymerization or hypofibrinolysis were identified with relatively high prevalence in patients with chronic thromboembolic pulmonary hypertension. Fibrinolytic resistance and high proportions of monosialyted ββ chains were linked to angiogenesis and growth of fibroblasts and endothelial cells, resulting in chronic inflammation and remodeling of pulmonary cells.

Other known cardiovascular risk factors, including body mass index, smoking, and diabetes mellitus, can also affect the fibrin network and CVD risk.

**Cancer**

Coagulation factors have been linked with malignancy for over a 100 years and high plasma fibrinogen levels, in particular, have been associated with cancer development and progression. Fibrinogen can be produced by some non-hepatocyte-derived cancer cells and present in the surroundings of tumors, such as in breast cancer.

A meta-analysis examining the prognostic effect of circulating fibrinogen in solid tumors showed a positive correlation between pretreatment fibrinogen levels and poorer survival (hazard ratio=1.51). Conflicting results came from studies on hematologic cancers, but overall patients with elevated baseline plasma fibrinogen levels had a significantly poorer clinical outcome.

Fibrinogen-deficient mice (Fga−/−) were protected against hematogenous pulmonary metastasis, but not tumor growth after intravenous injection of lung carcinoma and melanoma cell lines. Hirudin, a thrombin inhibitor, further reduced the metastatic potential of circulating cancer cells in Fga−/− mice, while plasmin depletion had no effect. In a colon cancer model, the thrombin-fibrinogen axis was shown to mediate primary tumor development, as it was diminished in Fga−/− mice.

The aforementioned associations between fibrinogen and cancer do, however, still require investigation as they do not prove causality. Several hypotheses can be made for the molecular mechanisms implicating fibrinogen in the initiation and development of neoplasms (Figure 2). First, fibrinogen binds growth factors, including vascular endothelial growth factor and fibroblast growth factor. Thus, extracellular matrix-residing fibrinogen may serve as a reservoir, controlling growth factor bioavailability and accessibility, and influencing cancer cell proliferation, inhibition of apoptosis, angiogenesis and metastases. For example, fibrinogen produced by epithelial cancer cells promotes lung and prostate cancer cell growth through an interaction with fibroblast growth factor 2.

Figure 2. Schematic diagram of pro-tumorigenic mechanisms involving fibrinogen. Fibrinogen binds and surrounds cancer cells, forming a structure that protects tumors from immune cells, in a process that may be enhanced by attracted platelets. By interacting with endothelial cells via intercellular adhesion molecule-1, among other receptors, fibrinogen contributes to the extravasation, cell migration and establishment of secondary tumors, while the link with leukocytes via αMβ2 results in the production of pro-inflammatory cytokines (e.g., interleukin-1β) rendering an inflammatory microenvironment that potentially favors tumor progression. The presence of fibrinogen surrounding the tumor, in addition to its protective role, may generate thrombotic events which could prompt a worse clinical outcome. Finally, fibrinogen’s ability to bind different growth factors further contributes to tumor maintenance. This figure was adapted from Simpson-Haidaris et al. and prepared using BioRender.com.

These studies suggest that modulating fibrinogen levels in cancer patients may have therapeutic potential. Lowering plasma fibrinogen, either via drug therapy or...
lifestyle changes, may help to prolong survival in cancer patients. Likewise, other approaches targeting fibrinogen-dependent interactions (e.g., inhibitors of fibrinogen-αβ interactions) may also prove useful in cancer treatment and/or prevention.73

**Neurological disorders**

The biological complexity of several neurological diseases involving the CNS, such as Alzheimer disease and multiple sclerosis, is not yet fully understood. However, the need to study CNS cells within their environmental context is clear.

The brain vasculature consists of dynamic metabolic structures that work as a continuum from artery to arteriole to capillary to venule to vein.8-14 The blood-brain barrier (BBB) is essential to separate blood from extracellular fluid in the CNS. The BBB is formed by endothelial cells that maintain critical interactions with other cells, together with a basement membrane that affords an anchor for many signaling processes at the vasculature.15 By providing a dynamic physical and metabolic barrier between the CNS and systemic circulation, the BBB ensures constant protection of the neural microenvironment from the influx of potentially harmful substances including plasma proteins, immune cells, pathogens and drugs, while maintaining the efflux of toxins and waste products.16-18 Disruption of the BBB is an early event that occurs in many neurological disorders, such as Alzheimer disease, in which, along with microglial activation and neuronal cell death, the neuropathological hallmarks include extracellular deposition of amyloid-β (Aβ) plaques and blood vessel walls, and the intracellular accumulation of neurofibrillary tangles containing phosphorylated tau proteins.19 Brain micro-hemorrhages are frequently observed in patients with Alzheimer disease, and BBB disruption correlates with disease progression.20 In animal models of Alzheimer disease, BBB leakage precedes other neuropathological alterations in the brain,21 suggesting that damage to the barrier is implicated in the initiation and progression of the disease.22 BBB disruption is also one of the earliest representative events in the pathology of multiple sclerosis.23 Indeed, BBB disturbance is linked to the inflammation and white matter injury that define this neuroinflammatory disorder.24,25 Fibrinogen may extravasate into the CNS upon such events. Once in the brain, fibrinogen can induce signaling networks via binding sites for multiple receptors and proteins, acting as a mediator of neurodegeneration and an activator of innate immunity.26

Fibrin deposits are found in early multiple sclerosis lesions and areas of demyelination in close association with inflammation and damaged axons.27 In Alzheimer disease, fibrin deposits accumulate within CNS blood vessels in conjunction with cerebral amyloid angiopathy.28 In the perivascular brain parenchyma, fibrin co-localizes with Aβ plaques,29 macrophages,30 areas of pericyte loss31 and dystrophic neurites.32

Fibrin formation exposes the cryptic epitope γ377–395, which binds with high affinity to the αVβ3 integrin on microglia and infiltrating macrophages, activating multiple signal transduction pathways to promote inflammatory responses. This is associated with antigen presentation, release of reactive oxygen species33 and secretion of the leukocyte-recruiting chemokines CCL2, and CXCL10.34 In multiple sclerosis this may lead to T-cell recruitment and local differentiation of myelin antigen-specific T helper 1 cells to promote autoimmunity and demyelination.35 In animal models of Alzheimer disease, fibrinogen was shown to accumulate in areas of dendritic spine elimination, even independently and distal to Aβ peptides that aggregate to form neurotoxic and stable oligomers, with ensuing cognitive impairment.36 The fibrinogen-mediated elimination depends on microglial αVβ3 receptor activation and generation of reactive oxygen species. However, the fibrin-Aβ interaction has an additive effect on poor outcome. Aβ can activate contact pathway coagulation to drive fibrin formation,37 protect fibrin from degradation38 and allow a constant inflammatory signal.

Fibrinogen contributes to neurological disease by inhibiting remyelination after vascular damage.39 Fibrinogen can activate bone morphogenetic protein (BMP) receptor activin A receptor type I and downstream BMP-specific SMAD proteins in oligodendrocyte progenitor cells, independently of BMP ligands.40 This prevents oligodendrocyte progenitor cells from differentiating into myelinating oligodendrocytes and promotes an astrocyte-like cell fate. Fibrin-M1-like activation of microglia41 and macrophages42 can also be toxic to oligodendrocyte progenitor cells and further impair remyelination.43 Another possible mechanism is through fibrin-induced phosphorylation of extracellular signal-regulated kinases and production of nerve growth factor receptor in Schwann cells, maintaining them in a proliferating, non-remyelinating state.44

Neurite outgrowth inhibition45 and glial scar formation46 may also be triggered by fibrinogen, leading to cerebrovascular pathologies. Fibrinogen inhibits neurite outgrowth by binding the αVβ3 integrin and trans-activating epidermal growth factor receptor in neurons.47 Inhibition of axonal regeneration occurs indirectly by prompting astrocytosis and stimulating the production of inhibitory proteoglycans that form the glial scar. Fibrinogen can carry a latent transforming growth factor-β that is activated when it encounters primary astrocytes, stimulating the production of neurocan, a strong inhibitor of neurite outgrowth.48 Consistent with these observations, reducing fibrinogen levels with ancord,49 manipulating the conversion of fibrinogen into insoluble fibrin with hirudin50 and interfering with fibrinolysis by tissue plasminogen activator51 all attenuated injuries and promoted regeneration and functional recovery. Similar results were also obtained after treatment with γ377–395 peptide52 or a monoclonal antibody against the same epitope,53 revealing an essential role for fibrin in peripheral nerve damage and repair.

In summary, fibrinogen can induce degenerative changes in the CNS through different mechanisms that initiate or potentiate neurodegenerative processes after vascular disruption (Figure 3A). While many studies have found that fibrinogen promotes neuroinflammation through binding to the αVβ3 integrin on macrophages and microglia, pericyte-deficient mice lack a significant neuroinflammatory response until late in the disease. These mice suffer from early BBB breakdown and accumulation of white matter fibrinogen that is associated with diminished blood flow and hypoxia. However, following white-matter injury, no changes were detected in astrocyte, microglia or macrophage responses or pro- and anti-
inflammatory cell profiles and/or numbers of astrocytes and microglia in the resting state. This suggests that fibrin(ogen)-driven neurodegeneration can also be inflammation-independent (Figure 3B).105

Association studies have correlated elevated plasma fibrinogen levels with cognitive decline, independently of inflammatory markers.109,110 Proteomic studies detected higher fibrinogen levels on platelets from subjects with secondary progressive multiple sclerosis.111 This highlights dysfunctional coagulation as a common thread among diverse neurovascular abnormalities. Fibrin(ogen) may, however, be beneficial in acute CNS injuries by delaying regeneration until the extracellular environment is conducive to repair.100

Pharmacological agents targeting fibrinogen or fibrinogen interactions with CNS cells or other players may have potential as therapeutics for neurological diseases. Such drugs could include agents that enhance fibrin(ogen) degradation, protect the BBB to limit fibrin(ogen) entry into the CNS, or selectively inhibit the interactions of fibrinogen and fibrin with their CNS receptors, αMβ2 or Aβ, while preserving the beneficial functions of fibrinogen.85

Figure 3. Schematic representation of the mechanisms linking fibrin(ogen), neurological diseases and cognitive impairment upon blood-brain barrier breakage. (A) The main components of the pathways that ultimately lead to neuroinflammation and neurodegeneration are described in this panel, including the interaction with Aβ peptides observed in Alzheimer disease. (B) An alternative mechanism that does not implicate inflammation. Increased fibrin(ogen) accumulation results in pericyte and oligodendrocyte loss, without affecting astrocytes or microglia. This will lead to microvascular dysfunction and white matter pathology. This figure has been adapted from Petersen et al.85 and Merlini et al.97 and created with BioRender.com. ACVR1: activin A receptor type 1; Aβ: amyloid-β; OPC: oligodendrocyte progenitor cell; ROS: reactive oxygen species; TGFR1: transforming growth factor-β receptor type 1; Th1: T helper 1 cells.
Microbial infections and allergic reactions

Fibrinogen is implicated in defense against pathogen invasion, for example in peritonitis. Recent findings from experiments in vitro and in vivo show that at the air-liquid interface formed following a skin wound fibrin can accumulate perpendicularly to generate a protective biofilm. These structures, which are an end product of clotting and fibrin formation, prevent blood cell loss from the wound but also block the entry and early proliferation of bacteria at the injury site. However, in other settings fibrinogen enhances bacterial virulence or contributes to the development and perpetuation of allergic reactions.

Certain bacteria express virulence factors that appropriate fibrinogen to facilitate their entry into the host, limiting the antimicrobial role of fibrinogen and protecting the organisms from pharmacological treatments. Virulence factors can also enhance bacterial proliferation and dissemination.

The anti- or pro-invasion effects of fibrinogen reflect the activity of bacterial virulence factors (Table 1) which have adapted to unique host microenvironments. For example, different murine models of Staphylococcus aureus endocarditis require distinct factors for valve colonization. Microbial adhesion and colonization in mice with mechanically damaged valves involve fibrinogen, whereas in a model of cardiac valve inflammation fibrinogen depletion with ancrod did not impair bacterial colonization. Bacterial volume increased in ancrod-treated mice compared to that in controls. Further comprehension of the roles of coagulation factors on bacterial virulence may lead to therapeutic strategies for the treatment of infectious diseases, particularly given the increasing demand to find a solution to antibiotic resistance.

In fungal infections, proteases contribute to inflammation through interactions with the kinin system as well as the coagulation and fibrinolytic cascades. In this context, the fibrinogen interaction with αβM2 is implicated, as it may further react with Toll-like receptor 4 (TLR4) in immune cells, resulting in a highly efficient signaling complex that regulates the development of antifungal reactions, but also allergic airway disease.

Fungal proteases cleave fibrinogen into cleavage products (FCP) which, together with αβM2 and TLR4, were found to be essential for fungal elimination by T and B lymphocytes, dendritic cells and macrophages. The fibrinogen hexamer can also inhibit fungal growth, perhaps due to low affinity fibrinogen-target receptor interactions. However, the putative αβM2/TLR4/FCP complex also triggered innate fungistic immunity, modest allergic airway hyper-responsiveness and neutrophilia. Interestingly, this αβM2/TLR4/FCP association has been described in unrelated settings, including endotoxemia and malaria. Thus, FCP that play a role in infection-mediated inflammatory responses have a pivotal role in the clinical outcome of patients with fung-induced autoimmunity.

Finally, fibrinogen also seems to be implicated in bacteria-driven hypersensitivity reactions. Pharmacological or genetic depletion of fibrinogen in mice improved the animals’ survival when they were challenged with high concentrations of lipopolysaccharide, and impeded the development of a variety of inflammatory conditions. In humans, afibrinogenemic patients have reduced responses in a delayed-type hypersensitivity reaction induced by exposure to bacterial antigens.

Obesity and diabetes

Nutrient excess leads to imbalances in cellular and molecular mediators of immunity and inflammation. These may drive metabolic dysfunction while triggering a hypercoagulable state, with elevated circulating levels of fibrinogen being among key coagulation components. Initial risk, severe morbidity and mortality outcomes for vessel-occlusive disorders correlate positively with the

| Fibronectin binding proteins A and B | • Contribute to biofilm formation  
| | • Bind plasminogen to facilitate staphylokinase activity (see below) |
| Bone sialoprotein–binding protein | • Prevents thrombin-mediated cleavage of fibrinogen |
| Extracellular fibrinogen–binding protein | • Formation of a protective shield of fibrinogen that prevents phagocytosis and innate immune cell recognition  
| | • Sequestration of fibrinogen preventing its interaction with neutrophils |
| Endocarditis- and biofilm-associated pilus-A | • Mediation of bacterial attachment to host fibrinogen, which permits building biofilms that shield bacteria from immune cell recognition, antibiotics, and urine flow (if applicable)  
| | • Contribute to nutrient acquisition |
| Coagulate and von Willebrand factor–binding protein | • Coagulate mediates formation of a fibrinogen-containing inner pseudocapsule that envelopes bacterial microcolonies  
| | • vWbp contributes to an extended outer dense protective layer  
| | • Both induce thrombin activation to form a fibrinogen protective shield around the bacteria against phagocytosis and innate immune cell recognition |
| Staphylokinase | • Contributes to the activation of plasminogen, which readily degrades fibrin to prevent microbial entrapment or permit bacterial detachment and dispersion throughout the host  
| | • Neutralizes the bactericidal effects of α-defensins secreted from polymorphonuclear cells |
degree of obesity. Thus, obesity represents a major risk factor for other pathologies, including thromboembolic events, CVD, diabetes, cancer and fatty liver disease.

Fibrinogen may be involved in the pathology of obesity. Levels of fibrinogen are higher in obese patients with type 2 diabetes than in obese subjects without type 2 diabetes. In addition, plasma fibrinogen levels correlate with fasting insulin levels and disease state advancement in noninsulin-dependent diabetics, and while insulin infusion decreases fibrinogen biosynthesis in normal subjects, insulin resistance/deficiency may contribute to hyperfibrinogenemia. Furthermore, fibrinogen from diabetic patients generates denser, fibrinolysis-resistant clots, while insulin treatment leads to changes in fibrinogen and a more permeable clot. These alterations have been attributed to the glycation of fibrinogen and its effect on fibrin clots, potentially contributing to the risk of thrombosis.

Mice fed with a high-fat diet developed fibrin(ogen) deposits in white adipose tissue and liver which co-localized with macrophage accumulation. In contrast to Fib Δ mice and mice without factor XIII A, Fib 390–396 A animals were protected from increased body weight with a high-fat diet, specifically at the fat mass level. These animals, with fibrin(ogen)-γ residues 590 to 596 replaced with alanine and therefore lacking an αβ-binding motif on fibrin(ogen), showed less systemic and local inflammation, demonstrated by lower levels of pro-inflammatory molecules, adipose tissue macrophages and smaller white adipose tissue adipocytes when compared to those of wild-type animals. In addition, the fibrinogen γ390–396A variant led to lower liver weight, steatosis, serum alanine aminotransferase and hepatic inflammatory markers, and conferred some degree of protection against the development of induced fatty liver disease. Glucose clearance and insulin sensitivity were improved, revealing improved glucose metabolism.

Thus fibrin(ogen)-driven inflammation, via leukocyte interactions in adipose tissue and liver, worsens obesity and increases its downstream harmful effects. Targeting thrombin or fibrin(ogen) may improve the morbidity of obesity-linked pathologies.

**Amyloidosis**

Amyloidosis is a group of disorders originating from mutations that cause conformational changes, typically involving β-sheet structures, in insoluble proteins. These then aggregate as extracellular amyloid fibril deposits in various organs. In systemic forms, amyloidosis can progressively induce organ dysfunction, and be fatal.

Fibrinogen-driven renal hereditary amyloidosis is a rare group of disorders with autosomal-dominant inheritance caused by heterozygosity for mutations in the αC-domain, which result in improper folding and amyloid formation followed by accumulation and deposition in the kidneys. Other elements present in the deposits can further contribute to fibrin(ogen) amyloid formation, namely amyloidosis-enhancing factor and serum amyloid A. The latter binds to purified fibrinogen and induces amyloid formation and spontaneous dense, matted fibrin(ogen) deposits, independently of thrombin. However, its involvement in renal amyloidosis has not yet been demonstrated.

Fibrinogen-derived amyloid deposits disrupt kidney structure and impair kidney function, effects that become more severe over time, with accumulation of the amyloid. Amyloidosis is associated with hypertension, nephrotic syndrome, vascular, cardiac and neurological implications. Fibrinogen variants are produced in the liver where they may rarely cause hepatic amyloidosis. In addition to the kidney, where deposits prompt renal failure, fibrinogen has different targets. It may also accumulate in vascular and cardiac walls, resulting in impaired endothelial function. This, together with nephrotic syndrome, hyperlipidemia and hypertension, facilitates atheroma formation and eventually results in coronary atherosclerosis. Fibrinogen may be the basis of neuropathic features as well as the symptoms of gut dysmotility in patients with fibrinogen amyloidosis. This image was adapted from Picken MM and created with BioRender.com.
syndrome, and renal failure. Several renal amyloidogenic mutations in fibrinogen have been described ([Online Supplementary Table S2](#)). Patients with these mutations do not have a bleeding disorder and, when measured, the clotting times of patients with these variants are normal, except those with p.Thr544LeufsTer24 who had a prolonged thrombin time and low fibrinogen level.

While the kidney is the predominant organ for fibrinogen-amyloid deposition, the pathology of hereditary fibrinogen amyloidosis is not restricted to involvement of this organ. Fibrinogen amyloidosis patients show a high incidence of cardiovascular atheromatous disease with a family history of coronary/vascular disease. Fibrinogen deposits are found in vascular walls and atheromatous plaques, associating fibrinogen variant amyloidosis and atherosclerosis. While nephrotic syndrome with hyperlipidemia and hypertension may facilitate atheroma formation, the cardiovascular findings are unlikely to be caused by renal failure alone. Thus, hereditary fibrinogen amyloidosis is a complex systemic amyloid disease that is associated with cardiac amyloid deposition, angiopathy and atheromatosis ([Figure 4](#)).

There are currently no treatments available to resolve amyloid deposits. Disease management consists of interrupting amyloidogenic protein supply with supportive care to failing organs, and transplantation. Hepato-renal transplantation appears to prevent disease progression and allows reversal of some organ dysfunction.

**Conclusions**

As the thrombin substrate for generating fibrin, fibrinogen has a critical role in controlling bleeding upon vascular injury, as well as being a major determinant in wound healing, tissue regeneration and mediation of inflammatory responses that help the immune system fight invading pathogens. However, several layers of evidence point to fibrinogen as a contributor in pathological settings ([Figure 5](#)). These contributions may result from altered plasma concentration, modified structural properties, or from the impact of polymorphisms on clot permeability, stiffness and resistance to lysis. The presence of fibrinogen in particular locations is a determinant in the development of disease. Here we have discussed human disorders in which the role of fibrinogen is supported by clinical data and animal models. Fibrinogen is also a likely protagonist in fibrotic and arthritic diseases. Continued research will allow a better understanding of these complex disease settings and the impact of fibrinogen. Whether the presence, quality or abundance of fibrinogen has a causal role, or is a consequence of the underlying pathology, should be a focal point. Such research will help to evaluate the usefulness of targeting fibrinogen in a variety of human disease settings.
